APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Statisticians (approximately 12) in the Home Civil Service—The Secretary, Civil Service Commission, 6 Burlington Gardens, London, W.1, quoting No. 2105 (February 12).

Assistant Lecturer in Chemistry—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (February 14).

Research Biologist (Scientific Officer Grade), and a Research Assistant (Assistant Experimental Officer Grade) for routine analysis, etc., as member of a team studying plankton ecology in relation to the fisheries—The Head of the Department of Oceanography, University College, Hull (February 14).

Laboratory Steward (Grade II) in the Department of Physics—The Clerk, Birkbeck College, Bream's Buildings, London, E.C.4 (February 14).

Chemist to take charge of the Plant Protective Chemistry Section—The Secretary, East Malling Research Station, East Malling, Maidstone, Kent (February 21).

Lecturer in the Department of Physiology—The Secretary, The University, Aberdeen (February 21).

Chemists (men and women) in the Scientific Officer Class and Experimental Officer Class of the Chemical Inspection Department, Ministry of Supply—The Ministry of Labour and National Service, Technical and Scientific Register, Room 669, York House, Kingsway, London, W.C.2, quoting F78/48A (February 28).

Superintending Analyst—The City Analyst, City Laboratories, Mount Pleasant, Liverpool 3 (February 28).

Microbiologist and an Organic Chemist in the Colonial Microbiological Research Institute, Port-of-Spain, Trinidad—The Under-Secretary of State, Colonial Office (Research Department), Palace Chambers, Bridge Street, London, S.W.1 (March 1).

Assistant Lecturer or Lecturer in Organic Chemistry—The Registrar, The University, Leeds 2 (March 1).

Senior Lecturer in Mechanical Engineering, Senior Lecturer in Aeronautical Engineering, Senior Lecturer in Civil Engineering, a Lecturer in Electrical Engineering, and a Lecturer in Mechanical Engineering, at Auckland University College, Auckland, New Zealand—The Secretary, Universities Bureau of the British Empire, 8 Park Street, London, W.1 (March 1).

Readership in Public Health at the London School of Hygiene and Tropical Medicine—The Academic Registrar, University of London, Senate House, London, W.C.1 (March 3).

Junior Physicist in the Radiotherapeutic Department—The Clerk to the Governors, St. Bartholomew's Hospital, London, E.C.1 (March 6).

Readership in Physics at Birkbeck College—The Academic Registrar, University of London, Senate House, London, W.C.1 (March 9).

Readership in Entomology at the London School of Hygiene and Tropical Medicine—The Academic Registrar, University of London, Senate House, London, W.C.1 (May 3).

Laboratory Assistant—The Secretary, Royal (Dick) Veterinary College, Summerhall, Edinburgh 9.

Entomologist for research into problems concerned with insects and other animals in the soil in connexion with agricultural problems, and an Entomologist or Zoologist (temporary) to study soil insects and other animals in relation to problems of forestry—The Secretary, Rothamsted Experimental Station, Harpenden, Herts.

Lecturer in Physics, and Assistant Lecturers in Geography, Chemistry and Physics—The Registrar, University College, Leicester.

Assistant Biochemist at the Courtauld Institute—The Secretary, Middlesex Hospital Medical School, London, W.1.

Director of Research for the Whiting (Calcium Carbonate) Industry—The Secretary, British Whiting Federation, 26 Claremont Road, Surbiton, Surrey

Research Assistant to investigate insect pests of pea crop—The Secretary, School of Agriculture, Cambridge.

Scientific Officers (2) for the Soil Survey of Scotland—The Secretary, Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen.

Histological Laboratory Technician, and a Bacteriological Technician—The House Governor, Canadian Red Cross Memorial Hospital, Taplow, Maidenhead, Berks.

Research Engineer for experimental stress analysis of the structures, wheels, etc., of vehicles both under static and operating conditions, a Research Physicist for investigation of general noise problems associated with the operation of I.C. engines and motor vehicles, an Information Officer, a Chemical Laboratory Assistant for general inorganic chemical analysis, and a Metallurgical Laboratory Assistant for general metallurgical examination of automobile engineering components—The Director, Motor Industry Research Association, Great West Road, Brentford, Middx.

HIGHER TECHNOLOGICAL EDUCATION IN BRITAIN

AMONG the unanimous recommendations of the report of the Percy Committee on Higher Technological Education, that for the establishment of a national council of technology received widespread support, and after announcing his intention to implement this recommendation, the Minister of Education in September 1947 appointed a 'working party' under the chairmanship of Mr. D. R. Hardman to advise on the establishment of a national council and on the principal steps to that end. All ten regional councils and academic boards recommended by the Percy Committee have already been constituted. National colleges have been established in several branches of technology and others are contemplated in the near future. Local education authorities were directed in Circular 133 issued by the Ministry of Education on March 19, 1947, to prepare their schemes of further education and plans for county colleges, as the basis for national action along the lines of the Education Act of 1944 ; and although here, as in the expansion of the universities, restrictions on building may hinder development, that delay affords a further opportunity for considering the long-term plans for the expansion of higher education as a whole.

The first meeting of the 'working party' revealed a large measure of agreement both on the general issue and on major questions of detail among its members. The 'party', which included Dr. J. E. Myers, Dr. A. E. Trueman, and Mr. F. W. Lawe, was satisfied that the case for setting up a national council had been established and recommended that steps be taken to that end with as little delay as possible, so that developments in training technologists as well as craftsmen, technicians and others may proceed along sound lines.

It is proposed that the general function of the national council should be to advise the Minister of Education on the national aspects of regional policy ; and although it will be an advisory and deliberative body, the possibility of executive functions, for example, such as might be involved in the certification of technological courses of graduate standard, is visualized. The 'working party' does not, however, altogether agree with the proposal in the Percy Report that the national council should be advisory to the University Grants Committee as well as to the Minister of Education. It is pointed out, quite correctly, that the University Grants Committee is itself the appropriate committee to advise the Government and to carry out certain defined functions in its own field. It is also true that the University Grants Committee has a province of its own separate from that of the proposed council; but it is by no means clear from this report where confusion will arise if the University Grants Committee is formally dependent for advice on technological education on the new council. The 'working party' recognizes that the closest consultation should exist between the University Grants Committee and the proposed new council in all matters of common concern, but it believes that this can be best achieved by the establishment of a joint committee of the Council and the University Grants Committee. No clue is given, however, to the responsibilities or terms of reference of such a joint committee, other than that it will deal with "matters relating to education of University standard". Since two specific functions of the council in respect of which it should advise the Minister of Education, namely, the planning of new developments, including national colleges, and the development of appropriate research in colleges, are listed separately, it would seem that the 'working party' has missed the point of this vital recommendation of the Percy Committee.

Even if Great Britain's resources of trained teachers of science and technology were not severely limited, and there were no severely competitive demands for trained man-power, the expansion of higher technological education and of the universities could not proceed independently without some close overall review, if not, indeed, a system of priorities. The expansion of technical colleges involves demands for equipment as well as buildings at precisely the point where university expansion is at present most handicapped. A link ensuring that the University Grants Committee is fully informed on proposals for higher technical education would seem almost essential.

Similar considerations apply to the question, which has been widely canvassed in recent years, of the development in Great Britain of institutions of the type of the Massachusetts Institute of Technology. Such developments must be evaluated from the point of view of university education as a whole, and also from that of technical education and the research organisation of the country. It should be remembered, moreover, that many industries look to the universities and not to the technical colleges for their leaders; and while the raising of the status of the technical colleges may tend to alter the balance, it is still true that as the scientific character of an industry becomes more pronounced, its demand for technologists tends to decrease and that for trained men of science to increase.

While the universities and the technical colleges, from the point of view of the expansion required for teaching and research, are in sharp competition with one another and with the demands of industry and of Government research establishments, the existing organisation which leaves the universities entirely outside the responsibilities of the Minister of Education, however logical and justifiable from one point of view, provides no obvious means for the overall review of resources. Such a review is imperative in order that duplication and waste of effort may be avoided and the output of technologists and of scientific workers related to real demand. The Percy Committee, as its report implicitly shows, was aware of this need; but admittedly it will not be easy to devise appropriate organisation to serve the need. Even in respect of teaching, account must be taken, as the Percy Committee also recognized, of the research associations and like institutions. Indeed, it seems that the Committee, in stressing the importance of bringing the research associations themselves into the closest possible relations both with the regional academic boards and with the national council, was aware of their value to industry as sources of trained technologists and scientific workers as much as from the research work actually carried out in their laboratories. From the point of view of technical education and the supply of technologists to industry, the position of the research associations requires appraisal, for it is as important as their contribution to the research structure of Great Britain.

The urgent need for closing this gap in the evaluation of universities, technical colleges and other institutions as suppliers of technologists and scientific men for industry, even if by some temporary expedient only, seems to have escaped the 'working party', in spite of its recognition that a national body is required which can advise on all questions bearing on education for industry and commerce, including training for the professions of management and for design in relation to industry and commerce. Even there, however, it would limit the responsibility of the national council to such aspects of those wider functions as fall within the jurisdiction of the Minister of Education. Nevertheless, it is recognized that technical and commercial education is a whole, from craftsmanship to management, and that problems in different parts of the field are interdependent; it is considered impracticable to extend the scope of the council to cover the whole field of further education. Accordingly it is recommended that the council should be entitled "The National Advisory Council on Education and Commerce". Indeed, the general impression left by the report is that departmentalism has considerably restricted the 'working party's' vision. The imagination and perspicacity which characterized the paragraphs dealing with the technical colleges in the Nuffield College Statement on "Industry and Education" five years ago are sadly lacking.

Detailed recommendations for the constitution of the proposed council are appended to the report. Besides the representatives of the regional councils and regional academic boards constituting the majority of the council, it is proposed that the Minister of Education should have the right to select the chairman and to appoint directly up to twenty members to ensure that important branches of technical and commercial education are adequately represented, and also, at his discretion, assessors from Government departments. The council would work through a competent standing committee of up to twenty-four members, with such advisory sub-committees as may be required, and provided with secretarial and other staff and office accommodation by the Ministry of Education.

There can be no doubt that even within the limited field visualized by the 'working party', the proposed council should do much to support and co-ordinate the efforts of regional councils to improve the status, the resources and the work of the old technical colleges, and to ensure that regional and local needs are adequately served both in respect of teaching and of research. It remains to be seen whether the national council itself will prove able to resolve the main difficulty of the qualifications to be awarded by colleges of technology, on which the Percy Committee itself was sharply divided. On this one point also the Percy Report contains ample evidence of the importance of establishing, at a high level, some interdepartmental means of obtaining an overall review of university needs and requirements and of those of the technical colleges, in relation to the country's needs and resources, even if only as temporary expedient until the broad lines of policy in university expansion have been determined and conditions permit that policy to be implemented without recourse to a system of priorities. There are questions here which concern not merely the Minister of Education but also the Minister of Labour and National Service and the Lord President of the Council, quite apart from the Chancellor of the Exchequer and the Minister of Works. Whether or not they can be resolved in part by the Advisory Committee on Scientific Policy or some other means without the establishment of a temporary special body remains to be seen. The departmental swathing in which the 'working party' would bind the new National Advisory Council on Education for Industry and Commerce would seem to preclude a resolute attempt to deal constructively with the problems of technical education in Great Britain.

GERMAN WAR RESEARCH

German Research in World War II

An Analysis of the Conduct of Research. By Colonel Leslie E. Simon. Pp. xi + 218. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1947.) 24*s*. net.

THERE are many lessons to be learnt in all fields of military art from a study of the conduct of the Second World War, but many of these will be out of date and misleading in ten years time. The important lessons are those which will remain true because they depend upon human nature and not on the particular stage of scientific and technical development at the time. Under this heading comes the question as to why Germany, whose men of science and engineers are among the best in the world, failed to mobilize fully her scientific and technical resources until it was too late for them to be effective. Colonel Simon's book sets out to give a review of their major achievements during the War, and to give also the principal reasons for their successes and failures, particularly from the point of view of the organisation of research and development.

Such a book must inevitably be handicapped by considerations of security, but the author gives an account of the more important weapons developed by the Germans on the air and army sides—naval weapons are not mentioned. This will be of considerable interest to the non-military scientific worker. To the man of science interested in British war developments, however, the most important chapters are those giving an account of the German organisations for research, development and testing, and their relation with the army and the production ministries.

Few will quarrel with Colonel Simon's main thesis that it was lack of liaison between the scientific and military staffs which led to the wastage of scientific and technical effort in developing unpromising projects, and in the frittering away of energy on a number of spectacular but strategically inferior weapons. Where the ultimate blame for this lay is not made clear by the author. One cannot help feeling that a deeper analysis would trace this lack of contact and understanding to two main causes: first, to the over-confidence of the military leaders after the initial success, which led them to neglect the development of weapons which would be necessary for the successful prosecution of the later stages of the War; secondly, to the "Führer Prinzip", which does not encourage the objective discussion and analysis of military requirements, bringing together the scientific man, production engineer and military staffs at the highest level. It may very well be that the German magnetic mine was a blessing in disguise to Great Britain, because its early defeat established the reputation of the scientific investigator with the public and the military, whereas in Germany it was the army, supported by the air force, which had all the initial success.

Colonel Simon points out another important circumstance which led to the development of weapons which were unsatisfactory either from the performance or the strategic point of view. This was the existence of a powerful armament industry with its own research and development establishments, which was able to put over its own ideas and projects without their being tested by an effective and impartial group at a central proving ground.

This book will be of great interest to all scientific men who work in, or have worked in, experimental establishments; it will be of even greater interest to those who have also worked at the headquarters of the services or supply ministries. It contains an admirable account of the conditions under which the German men of science worked, which were excellent from the point of view of equipment and amenities, but deplorable in the lack of real co-operation from the military leaders.

MODEL RESEARCH IN HYDRAULICS

Scale Models in Hydraulic Engineering

By Prof. J. Allen. Pp. 407 + 35 plates. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1947.) 30*s*. net.

THIS is the book of the Manchester School for hydraulic model research, closely connected with the names of Reynolds, Gibson and Allen. The hydraulic model experiments begun here by Osborne Reynolds in 1885 were most probably the first systematic attempt in this line. It was not until the very last few years of the nineteenth century that Engels introduced this work on the Continent, and nearly thirty more years elapsed before John R. Freeman convinced the American hydraulic engineers and others that hydraulic model research on a great scale is a powerful means of solving problems connected with many hydraulic constructions.

Nowadays there are more than a hundred hydraulic laboratories engaged upon this work. These laboratories can be divided into two groups, very unequal in numbers: the overwhelming majority in the United States and on the Continent of Europe, using big models, and the British laboratories, which seem to have the monopoly of the really small-scale models.

It is well known that the chance of discrepancies between the model and the prototype increases as the scale-ratio is higher. Prof. Allen devotes a large part of his book to proving that models with very high scale-ratios can be used with success, provided they are well-designed and operated judiciously. These models always have to be strongly distorted: the reduction of the horizontal dimensions (x) is much more pronounced than that in the vertical direction (y). In extreme cases the vertical exaggeration ($x : y$) has been a hundred and more: in the first Severn model, $x = 40{,}000$ and $y = 366$; the Seine model of Vernon Harcourt was characterized by $x = 40{,}000$ and $y = 400$. At present these very high ratios seem to be confined to preliminary experiments which may help in designing another larger model. In the latter, x may vary between 2,500 and more than 10,000; y from 60 to 400; $x : y$ from slightly more than 10 to 85.

A typical example of a successful model of this type is the Rangoon tidal model ($x = 8{,}060, y = 192$). As in many others, the bottom consists of carefully selected sand which imitates the transport observed in the Rangoon estuaries and on the adjacent bars. Starting from the soundings of 1875, the model has succeeded in reproducing the conditions of 1897, 1910 and 1932. The tests have been carried up to and beyond 1982. The model indicates that the deterioration of the Rangoon approaches is unlikely to continue much longer, and Prof. Allen convinces us there is a fair chance that this prediction may come true.

'Continental' practice is gradually developing in the direction of small-scale models: the well-known Mississippi models in Vicksburg have $x = 2{,}000$ and $y = 100$. The Delft laboratory is actually constructing a model of the estuaries and tidal rivers in Holland in which $x = 2{,}400$ and $y = 64$, a vertical exaggeration of 37·5. It is true that these models have fixed bottoms, so that they are not subject to the complication of sand movement, but their scales overlap the recent British ones. Prof. Allen mentions the Great Ouse and Wash model, in which $x = 2{,}500$ and $y = 60$, and in the James Forrest Lecture before the Institution of Civil Engineers which Prof. Allen delivered in May 1947, attention is given to the newly designed model of the Firth of Tay with $x = 1{,}760$ and $y = 144$. In this lecture Prof. Allen explained why British small-scale models with movable bottoms give good results and Continental ones do not. The vertical scale ratio y is limited by the speed V of the current in the channels: from an empirical relation it may be deduced that the upper limit of y is proportional to $V^{3\cdot7}$. I would like to direct attention to the fact that all the British models have to do with parts of the world where high tides and strong tidal currents occur: they would fail if the method were used to reproduce the conditions on the coasts of Denmark or New Jersey or Holland.

The theoretical considerations which underlie the experiments are expounded in the first chapters of the book. Similarity in friction losses is extensively discussed. It is curious that the Bazin formula (which dates from 1897) is taken as a starting point; only little attention is given to the later work of Prandtl, Kármán and their successors, and the interesting investigations at the Imperial College of Science and Technology, London, by Prof. C. M. White and his collaborators are not mentioned at all.

It is to be regretted that in hydraulics so much use is still made of formulæ (like that of Bazin) which describe the results of a number of experiments, but which are not based on adequate theoretical considerations.

For Continental students of hydraulics, the chapters dealing with tidal models are the most interesting ones of the book. They give a survey of how the work in the United Kingdom is done, why it is possible and what its limitations are. Prof. Allen's work will help to create a better mutual understanding between the workers on both sides of the North Sea (and of the Atlantic Ocean).

Other investigations than the tidal ones are not forgotten. The author mentions the paradox that models of small objects such as spillways, sluices and weirs sometimes have to be larger than those of estuaries; the reason for this is explained.

The chapter on waves shows that in several parts of the world much has been done and is being done in order to solve the many problems connected with waves of several kinds. Mutual information is necessary if we want to know more of the impact of breaking waves. The bore or eagre is dealt with, and two beautiful plates give a picture of this phenomenon in the Severn. It is not clear why the hydraulic jump is treated together with the waves: it is no real wave at all, because conditions in it are permanent.

Valuable details of the construction and operation of the models complete this book. We may consider it as a welcome addition to the literature of hydraulics.

J. TH. THIJSSE

CEREAL RUSTS

The Nature and Prevention of Cereal Rusts as Exemplified in the Leaf Rust of Wheat

By Dr. K. Starr Chester. (Annales Cryptogamici et Phytopathologici, Vol. 4.) Pp. xvi + 270. (Waltham, Mass.: Chronica Botanica Co.; London: Wm. Dawson and Sons, Ltd., 1946.) 5 dollars.

"THE most destructive disease of the world's greatest food crop", is Dr. K. Starr Chester's valuation of *Puccinia triticina*, the orange leaf rust or brown rust of wheat. The reader who, misled by the short title "The Cereal Rusts", turns to this book for a comparative or systematic account of the cereal rusts will be disappointed. He will find instead a valuable monograph on the brown leaf rust of wheat, in which the author summarizes his own researches and gives a comprehensive review of the literature with a bibliography of nearly five hundred titles. In preparing the book the author has translated a number of the major Russian contributions and made them available to other workers by depositing copies in several North American libraries.

Unlike the more familiar black stem rust (*Puccinia graminis*), the brown leaf rust overwinters in most of its geographical range in the mycelial stage on autumn-sown wheat or on volunteer wheat plants. Only in exclusively spring wheat areas, like the Canadian prairies, does the long-distance transport of spores from massive sources on autumn-sown wheat assume a dominant role. Reverse migration from cooler regions has been shown by Chester in the United States and by Mehta in India to recolonize areas where summer temperatures are too high for survival on wheat. Only in the Lake Baikal region of eastern Siberia does an alternate host regularly play a part in the annual cycle of the rust. *Isopyrum fumarioides*, a common biennial ranunculaceous weed of wheat fields in this area, regularly bears the æcidial stage and is the only means by which the rust survives the winter in this isolated area of wheat cultivation. European species of *Thalictrum* have been infected from wheat artificially, and new physiological races of the rust have been produced on this host by hybridization; but under natural conditions *Thalictrum* is apparently never affected by *P. triticina*. What are the chances of new races developing on *Isopyrum* in eastern Siberia and being borne by uredospore inocula to far distant areas where the brown leaf rust has dispensed with sexual reproduction on its alternate host? Dr. Chester thinks the possibility remote, as the Lake Baikal area is isolated by immense barriers of desert and mountain from other wheat-growing areas. In his account of dissemination the author gives reasons for considering that while dissemination of uredospores may occur over hundreds of miles as in North America and India, nevertheless the Lake Baikal area, Australia and South America are effectively isolated from the rest of the world's wheat-growing areas. Despite this comforting conclusion, *P. triticina* now exists in many physiological races which must have arisen by hybridization on *Isopyrum* or by mutation in the uredinial stage on wheat.

In trying to reduce many of these races to synonymy by introducing the notion of *race-groups*, the author will no doubt provoke criticism. However, this innovation allows him to explain the known reactions of wheat varieties to races of leaf rust in terms of the inheritance of a dozen or fewer hypothetical 'resistance-susceptibility' factors. Physiological races of the rust differ, it is suggested, in their ability to develop in the presence of some combinations of these factors. This leads to an interesting hypothesis as to the nature of the factors involved. "Resistance is commonplace, susceptibility is the rare exception. . . . It is not so much a question of what defences all other plants have that these susceptible varieties lack, as of what positive qualities these varieties have that all other plants lack." The author considers that this role may be filled by certain specific plant proteins, required by the fungus for its metabolism. Of the various kinds of evidence brought forward in support of this hypothesis those based on serological arguments are the least convincing. However, the idea should stimulate experimentation even where it fails to command assent. It falls into line with the concepts of Lwoff developed in his "Évolution physiologique", and with recent work in America and Europe on X-ray induced mutants in moulds and other fungi.

The economic importance of *Puccinia triticina*, according to Dr. Chester, has been unwarrantably under-estimated in face of the greater practical and academic attention focused on the black stem rust, *P. graminis*, with its alternate host on barberry. Extensive data are brought forward to show that, from being looked upon as harmless in Australia and the United States in the early years of this century, and relatively unimportant in the 1930's, brown leaf rust is now regarded as a severely destructive disease on half the wheat acreage of the United States, the U.S.S.R. and China. Attacking the crop earlier than stem rust, *P. triticina* represents a constant drain on the plant, less spectacular than the end-of-season epidemics of stem rust, but every few years reaching disastrous proportions over a large area of North America, as in 1938 when Thatcher wheat, bred for resistance to stem rust but susceptible to brown leaf rust, was destroyed over millions of acres. The importance of *P. triticina* has been confirmed by recent experiments in Canada by Peturson, Newton and Whiteside. In Britain this disease, like the powdery mildew, is common but is usually regarded as of little economic importance. This view appears to be supported by reiteration rather than by experiment, and it may be questioned whether any obviously destructive leaf disease can be dismissed as unimportant without carefully designed experiments in which yields of infected and healthy plots can be compared side by side. The evidence now brought forward should make us think again about *P. triticina*.

In a work of this magnitude, dealing with so many aspects of plant disease, every reader will find details to criticize and points with which he will disagree. The format of this book is larger than that of the earlier volumes in Dr. Frans Verdoorn's *Annals Cryptogamici et Phytopathologici*, and the work may stand awkwardly among its fellows on the library shelf. It is, however, a valuable addition to the literature of plant pathology.

P. H. Gregory

CONTROL OF THE GERMINAL EPITHELIUM

Contribution to the Knowledge of the Influences of Gonadotrophic and Sex Hormones on the Gonads of Rats

By J. H. Gaarenstroom and S. E. de Jongh. (Monographs on the Progress of Research in Holland during the War.) Pp. viii+164+8 plates. (New York and Amsterdam: Elsevier Publishing Co., Inc., 1946.) 8 fl.

THE idea of publishing a series of monographs on the progress of research in Holland during the recent war is an excellent one. The present volume is the seventh in the series, and consists of two main sections, and an appendix dealing with a number of diverse experimental observations. The first section concerns the hormonal factors on which the maintenance of testicular activity depends. The second deals with the corresponding aspects of ovarian physiology. Both sections are reports of experiments on rats, a fact which has to be borne in mind when generalizing the results. These show that testosterone can maintain the germinal but not the interstitial elements of the testes of rats the pituitaries of which have been removed, and that it therefore has a gonadotrophic function independent of the pituitary. The testicular involution which occurs as a result of œstrogenic stimulation can also be prevented by testosterone, and this Gaarenstroom and de Jongh interpret as being due not to any antagonistic effect of the androgen on the œstrogen, either in the pituitary or the circulation, but to the direct stimulating effect of the androgen on the testis.

This is an interesting conclusion, the more so because it diverges somewhat from previous explanations of the inhibiting influence which androgens have on the results of œstrogenic treatment. From it, and from observations on the differential effects of the two pituitary gonadotrophic hormones, Gaarenstroom and de Jongh build up a general theory of the control of spermatogenesis. Their view is that one pituitary gonadotrophic fraction stimulates the interstitial cells of the testis to produce androgenic hormone, which in turn activates the spermatogenic cycle of the germinal cells, the initial development of which is under the control of the second pituitary fraction. It is a neat theory, and there is no doubt that it helps to interpret a number of diverse observations. But it does not account for all.

The section on the ovary does not lead to such clear-cut conclusions, and is certainly more controversial. But it, too, is most stimulating to thought, and like the section on the testis, will have to be studied by all workers who are concerned in the study of the development and control of the germ cells.

S. ZUCKERMAN

RESEARCH ON THE TREMATODA

The Trematoda of British Fishes

By Dr. Ben Dawes. (Ray Society, Vol. 131 for the Years 1944 and 1945.) Pp. viii + 364. (London: Bernard Quaritch, Ltd., 1947.)

THIS book is a worthy companion to the same author's book, "The Trematoda" (Cambridge University Press, 1946). The author modestly says that he does not claim to have given an exhaustive account of the trematodes of British fishes, and it has naturally been difficult to decide whether some marine fishes caught off the coasts of the British Isles should be classified as British species or not. New records of species parasitic in particular hosts will certainly be made from time to time as fishes are caught and examined, so that no systematic account written now can hope to be complete. But Dawes has collected, in the 286 pages of classification and systematic descriptions of species in this monograph, the information available at present. To this he adds 26 pages of references to the literature and a list of the British fishes in which the trematodes occur. Both these latter features greatly add to the value of the book. Five chapters give concise accounts of the Platyhelminthes, the three orders of Trematoda and the morphology of the Monogenea, the Aspidogastrea and the Digenea. Many zoologists will find these chapters valuable, quite apart from the systematic details which follow them. A concise account of the Monogenea will be especially useful.

The preparation of this book must have entailed a great deal of labour and care, and it is gratifying to find that the publishers have given it worthy production. It is written in the author's clear and concise style, and the quality of the fifty-one drawings maintains the standard reached in the author's other book mentioned above.

No doubt these two books will stimulate others to take up the many problems which their author outlines. Experimental work is especially needed, and it is likely that, before long, work which is now going on will provide us with a sterile trematode in artificial culture, the study of which will greatly add to our knowledge of the physiology of all the Platyhelminthes. It is not impossible that we shall also learn from this work facts which will lead to a better understanding of the physiology of the Nematoda also.

The beneficent effects of such studies upon the control of diseases of man and animals caused by these organisms would be so considerable that it is to be hoped that experimental biologists will no longer neglect this fascinating field of work. So great, indeed, is the damage done to man and to his food supplies and civilization by the helminths that a strong case could be made out for the organisation of a planned attack upon them. If such an attack were planned, there is no doubt that medical men and veterinarians would heartily co-operate in it; but, before it could succeed, the basic work must be done, and that is work for the experimental biologist who understands the fundamental physiological problems involved and has the experience and training necessary for the study of them.

G. LAPAGE

A COLLECTOR'S TRAIL

The End of the Trail

By Willoughby P. Lowe. Pp. iv+178+18 plates. (Exeter: James Townsend and Sons, Ltd., 1947.) 20s. net.

IN this book, Mr. Willoughby P. Lowe gives some account of his work as a collector for the British Museum (Natural History), which has taken him into many far regions of the world. We say "some account", for Mr. Lowe has spent a life-time in quest of rare creatures and in visiting the most out-of-the-way places. In this by no means bulky volume, which is a successor to an earlier work, "The Trail that is Always New", there are chapters devoted to a winter in Tunisia, no less than four visits to Indo-China, a journey across the Sahara to the Hoggar Mountains, a trip to Tanganyika, collecting in the Ashanti Forests of the Gold Coast, and a visit to the northern territories of the Gold Coast. The reader, greedy for more, feels that these chapters are all too brief; for example, each visit to Indo-China, that ornithological paradise, might well be the subject for a volume to itself.

The facts are related in a style so studiously restrained that it might almost be termed bald, but an occasional descriptive passage gains in impressiveness from its setting. When writing of his work in Tonkin, which was mostly done just north of Hanoi, the capital, he tells us that "... we had special permission to do what we liked. Every day we wandered along the winding paths, cut in the precipitous hillsides where grew magnificent trees, flowering shrubs and ferns. Orchids hung in the shadow of the dark green foliage, and begonias and other beautiful vegetation grew in such utter confusion as to be bewildering. On the ground were fallen fruits, nuts and seeds of every description. Large macaque monkeys made their home along the paths winding in gentle gradient up the mountain slopes and dashed through the tree-tops for safety."

In this wonderful countryside a great variety of life of all kinds was encountered, and a large number of interesting specimens were obtained, including many birds and mammals new to science. The rough list of novelties discovered on this and on other trips which is given at the end of the book is impressive indeed. It embraces many newly described forms of mammals and birds and is an eloquent testimony to the author's hard work as a collector for the Museum. It also gives us a hint, though scarcely more than a hint, of a life not only well spent but also of vast and varied experience; in short, a life to be admired and envied. This book should enthral the young naturalist and set him dreaming of strange creatures in strange lands.

F. PITT

GENETICS AND ALGAL LIFE-HISTORIES

By Dr. KATHLEEN M. DREW
Department of Cryptogamic Botany, University of Manchester

IN a recent brief review, Barber[1] has directed attention to the need for incorporating results obtained from genetical and cytological studies of the algæ into the general body of genetical science. I am grateful to Prof. Barber for stimulating interest in this field of study, because most genetical work up to the present has been concerned with groups of plants having the Hofmeisterian type of life-history. It is quite unknown to what extent the algæ would lend themselves to extensive genetical investigation and whether data obtained from such experiments would conform to the genetical concepts accepted to-day for the higher plants.

In particular, Barber considered the interpretations of my cytological findings[2,3,4] in *Spermothamnion Turneri* and *Plumaria elegans*. He concludes: (1) that the plants of *S. Turneri* with ninety chromosomes are hexaploid and not triploid and that "it is thus possible that in this species two closed diplobiontic cycles exist"; (2) that the plants with thirty chromosomes are allodiploids; and (3) that the triploid–hexaploid cycle is "fast becoming genetically isolated from its progenitors and will pursue, if it can survive, its own evolutionary pattern". He points out that by not keeping the two cycles distinct, the genetical and evolutionary implications are obscured and "the primary significance of the *completed* sexual cycle is in danger of being overlooked". In *Plumaria elegans* Barber considers that the "genetical situation is entirely analogous to that obtaining in apomictic Angiosperms such as Taraxacum, Hieracium etc., and the asexually propagated bananas and oranges", and that this alga "shows both a normal floridean haploid–diploid diplobiontic cycle (to use the current algological terminology) and a genetically isolated triploid haplobiontic cycle".

With the point of view put forward by Prof. Barber in mind, the available evidence regarding the life-histories of these two floridean algæ are here reconsidered together with the fundamental considerations involved.

While a comparison of the observations in the angiosperms and the red algæ suggests that the fundamental mechanism of chromosome behaviour is the same in both groups, yet certain broad concepts applicable to the angiosperms cannot be transferred without modification to the algæ. The following remarks apply particularly to those red algæ with the *Polysiphonia*-type of life-history. In such algæ the separation of the haploid and diploid phases of the sexual cycle into two physiologically separate entities (omitting any consideration of the cystocarp for the time being) contrasts sharply with the angiosperms, where the haploid is considerably reduced, enclosed in and physiologically dependent on the diploid, which, in fact, exhibits sexual characters.

This somatically separate existence of the two phases is one of the facts which necessitate modification of certain concepts accepted for higher plants. In the first place, the 'progeny' of the diploid phase is the haploid phase and vice versa. While the same is strictly true in the angiosperms, the succeeding diploid phase is referred to as the 'progeny' of the previous diploid. The completion of the gametophyte–sporophyte cycle in these algæ is dependent on the successful establishment, maturation and reproduction of two separate individuals, possibly with different sets of conditioning factors.

Secondly, while the sexual organs are usually restricted to the gametophyte and the tetrasporangia to the sporophyte in such algæ, cases are recorded (especially in the Ceramiales) where, with varying degrees of frequency, both sexual organs and sporangia occur on the same individuals. Whether these individuals are haploid or diploid is unknown except in the cases of *Spermothamnion Turneri*, where cytological evidence shows that the diploid bears both functional diploid sex organs as well as sporangia in which meiosis occurs, and *Nitophyllum punctatum*[5], where sporangia occur on the haploid gametophyte but undergo no reduction division. These examples contrast with the diploid gametophytes of the Bryophyta and Pteridophyta, which usually bear sex organs only. In the latter case, the sequence of reproductive phases and the fundamental gametophyte–sporophyte cycle persists and is dependent evidently on factors other than the chromosome number; but in the algæ cited above the gametophyte–sporophyte cycle is either in the process of being established or is upset. If it is upset, it can be considered either an abnormality or an example of the transference of sexuality to the diploid as has happened in the angiosperms. These examples in no way invalidate Sharp's[6] contention that both genetic and non-genetic factors are concerned in the determination of sex as well as of life-histories. The cystocarp of the Florideæ demonstrates that chromosome number is not the predominant factor in determining the sequence of phases, for in some families it has the chromosome number of the gametophyte and in others the chromosome number of the sporophyte.

Thirdly, the formation of triploids and tetraploids becomes possible, and indeed probable, as a result of the occurrence of sex organs on the diploid, as is shown by *S. Turneri*. The fertilization of the carpogonium on a diploid by a haploid spermatium or vice versa and the production of a triploid involves no abnormality in the formation of the gametes. It is comparable to the diploid × tetraploid cross in the higher plants and not with the forms which originate as the result of some abnormality, as in cases where meiosis is nullified or suppressed or syndiploidy occurs. The genetical consequences are different in the two types.

With these general remarks as a background, the evidence available for *S. Turneri* is now summarized. Along the British coast, plants with 30, 60, 90 and 45–50 chromosomes occur. The same is true for the Atlantic coast of North America in the vicinity of Woods Hole, with the exception that there is only indirect evidence of the occurrence of plants with thirty chromosomes. In the earlier work, I regarded thirty chromosomes as the typical haploid chromosome number. Arguing from the genetical point of view Barber suggests that fifteen is the haploid number. The only other species of this genus for which the chromosome number is known is the Pacific species *S. Snyderæ* (*loc. cit.*, ref. 7), and this has thirty-one. At present, therefore, no definite conclusion about the haploid number can be reached.

The British plants of *S. Turneri* with thirty chromosomes bear sex organs and cystocarps and occasionally undivided sporangium mother cells, sometimes healthy, sometimes degenerated. Plants with sixty chromosomes, particularly those in

American waters, are characterized by the occurrence of both functional sex organs and normal tetrasporangia. A normal reduction division precedes the formation of the tetraspores, but no reduction division precedes the formation of the carpogonium. These American plants are known to produce cystocarps, the chromosomes of the divided carpogonium nucleus and the nuclei of the gonimoblast numbering approximately 120. (There are great technical difficulties in obtaining accurate counts of these high numbers; but details of the degree of accuracy reached have been given (*loc. cit.*, ref. 10). Two gonimoblasts (one American, one British) with approximately ninety chromosomes have also been seen and presumably originated from the fusion of sexual cells one with thirty and the other with sixty chromosomes. With the exception of one bearing a degenerated procarpic branch, no reproductive organs had been found on plants known to have ninety chromosomes. The existence of plants with approximately half this chromosome number, that is, 45–50, suggests the occurrence of an irregular meiosis in tetrasporangia on the plants with ninety chromosomes.

In *S. Turneri* certain facts suggest that the production of triploid plants is not necessarily a rare phenomenon; on the contrary, it may be occasional or even common. The facts (1) that triploid plants (with ninety chromosomes) were found on both sides of the Atlantic among the comparatively few plants of known chromosome number, and (2) that, among the still fewer nuclei available in gonimoblasts in a suitable condition for counting, two were triploid support this view. While the evidence suggests the existence of a 45–50 ⇄ 90 cycle, it appears to me from a consensus of evidence that it is not improbable that these plants reproduce most frequently by vegetative means. If there is a tendency for such a cycle to become genetically isolated, the repeated formation of plants with ninety chromosomes must ultimately result in the production of several genetical strains. It is possible that the formation of the triploid is easier to accomplish in the algæ than in the flowering plants, where the tetraploid × diploid cross is difficult to effect, since environmental conditioning factors such as size relations, endosperm, etc., may be fewer. On this there must be, however, a suspension of judgment until investigations have been extended. It should be noted that if it is accepted that plants with ninety chromosomes are triploid, a difficulty arises in finding a suitable designation for plants with 45–50 chromosomes.

In *Plumaria elegans* sexual plants with thirty-one chromosomes, tetraspore plants with sixty-two and parasporangia-bearing plants with ninety-three occur. The method of origin of the triploid is unknown; but it is possible that it originated in a manner similar to that of *S. Turneri*, that is, by the fusion of a haploid with a diploid gamete. Alternative possibilities that suggest themselves are the fusion of the diploid fusion nucleus with the haploid nucleus of the auxiliary cell or the fusion of the nuclei of two spermatia with the carpogonium nucleus. Unlike the triploid of *S. Turneri* and, in fact, all triploids, that of *P. elegans* has a special type of spore, the paraspore, which reproduces the triploid. Since parasporangia develop only on triploid individuals, it seems permissible to assume they represent a morphogenetic expression of the triploid condition. A comparison of the vegetative propagation of triploid angiosperms with the paraspores of *P. elegans* is no more than a broad biological analogy.

The triploid of *P. elegans* resembles those of angiosperms, however, in having a considerably wider distribution than the haploid and diploid. In this connexion it should be pointed out that the reproduction of the triploid is dependent only on the successful production and germination of the paraspores, whereas the survival of the haploid and diploid is interdependent and depends on the completion of highly specialized reproductive processes. There is nothing to suggest that this triploid is being formed repeatedly, and this being so, it is isolated genetically from the sexual cycle. Tetraspores develop occasionally on this triploid but were too rare for the details of the nuclear divisions to be followed.

Polyploidy, involving specific differences like that occurring in the genera *Chrysanthemum* and *Solanum*, may also occur in the red algæ, and a study of genera such as *Polysiphonia* and *Ceramium* might yield interesting results.

In the algæ, as in the higher plants, it seems possible that autopolyploids may arise by the doubling of the chromosome number in the vegetative nuclei. *Spermothamnion Turneri* has multinucleate cells, and in one of these a nucleus with at least fifty-four chromosomes occurred, all the other nuclei having approximately thirty. Likewise in the polysporangia of *Spermothamnion Snyderæ*[7], nuclei with two or even three multiples of n occurred in the same sporangium. As some nuclei were observed coalescing, this probably provides the explanation of the varied chromosome numbers. Coalescence did not appear to stop meiosis entirely, but the majority of the sporangia on such plants degenerated before maturity.

These observations have all been based on plants growing in Nature, and show the need for more extensive experimental genetical work on the algæ under conditions of culture. A satisfactory culture technique is a preliminary requisite, however, and while some of the simpler forms have been cultured successfully[8] little has been achieved with the more complex marine forms. A preliminary attempt of mine has had some success, and Hassinger is reported by Hartmann[9] to have succeeded in culturing *Callithamnion collymbosum* and to have analysed genetically interesting deviations. A full account of this work is not yet available.

In his article Barber also raised questions of terminology, and I agree that triplo- and polybiontic are unsuitable terms. I[10] have discarded these together with haplo- and diplobiontic and suggested that it would seem more exact to state that the life-history is morphologically mono-, di, tri- or polyphasic and cytologically mono-, di-, tri- or polyphasic. I still adhere to this, these terms being intended to convey a summary of the morphological and cytological facts of each case and nothing more. Such a summary is needed in the algæ where there may be more than one haploid or diploid phases, as in some Ectocarpales and the Florideæ, for example, and where forms such as *S. Turneri* and *P. elegans* occur. The terms haplont, diplont and diplohaplont express the relative length of the n and $2n$ phases.

I have defined life-history[10] as "the observed sequence or sequences of somatic and nuclear phases known for the species under consideration". Life-history, therefore, is not synonymous with completed sexual cycle, which is always a cyclic sequence of two nuclear phases requiring no cytological qualifying term, since it is independent, to a certain extent at any rate, of chromosome number. In *S. Turneri*, for example, it is conceivable, but not proved, that the life-history includes two or even three completed sexual cycles, the 30 $\rightleftarrows$ 60, 60 $\rightleftarrows$ 120 and 45–50 $\rightleftarrows$ 90. Whether or not they are closed independent cycles cannot be decided on the evidence at present available. Should they be independent, the evolutionary implications would be all the greater. In *P. elegans*, on the other hand, the life-history includes only one completed sexual cycle and the triploid appears to be a 'dead-end' from the evolutionary point of view.

Thus, while agreeing with Prof. Barber up to a point, I have endeavoured to show that life-histories in the algæ are conditioned by non-genetic as well as genetic factors, and that, until more data are available, some restraint in applying genetical concepts based on the higher plants should be exercised.

I am also making a plea for wider and more extensive studies of the life-histories in the various classes of algæ. It is now recognized that while the Hofmeisterian cycle provides an adequate account of the life-history of Bryophyta, Pteridophyta and Spermatophyta, it does not suffice to describe the many types of life-history to be found in the algæ. A knowledge of morphology, physiology and cytology as well as of genetics is necessary for an analysis of the factors conditioning the life-histories in this group of plants and for an understanding of how the gametophyte–sporophyte cycles of the higher plants arose.

BIOCHEMICAL REACTIONS OF CHEMICAL WARFARE AGENTS

THE true nature of Greek Fire is still wrapped in mystery and it is difficult to decide whether its use constituted chemical warfare. Chemical warfare, as we know it, was employed only in the First World War (1914–18), when mustard gas and phosgene were used and the study of their pathology was commenced. Work on the nature of these agents proceeded slowly from 1920 until 1939, when there was increased interest in poison gas. Since the Second World War ended, some of the work which was carried out for the British and American Governments has been released, or 'declassified' as the Americans say, and been published. The Biochemical Society arranged a symposium held at the London School of Hygiene and Tropical Medicine on some aspects of the biochemistry of these substances on December 13.

In introducing the symposium, Dr. Malcolm Dixon described how much of the biochemical research work was carried out by three extra-mural teams under Prof. R. A. Peters at Oxford, Prof. A. Wormall of St. Bartholomew's Hospital, London, and himself at Cambridge. Similar teams had worked on the problems in the United States. Much of the matter has interest apart from the original purpose of the investigations. In fact, many of the substances developed for use in the event of chemical warfare have found direct peace-time applications. Examples of this include the British anti-lewisite (*B.A.L.*), a general remedy for arsenical poisoning; di*iso*propylfluorophosphonate (*D.F.P.*), which is being used as a parasympathomimetic drug in treatment of myasthenia gravis; and methyl *bis*(β-chloroethyl)-amine or nitrogen mustard, used in palliation of Hodgkin's disease.

Chemical Reactions of Mustard Gas

Dr. A. G. Ogston gave the first paper of the symposium, dealing with "The Reactions of Mustard Gas in Aqueous Solution". Earlier work, starting with that of R. A. Peters and E. Walker (*Biochem. J.*, **17**, 260; 1923), on the kinetics of the hydrolysis of mustard gas in water had shown that the reactions of hydrolysis and substitution are of the 'SN_1' type described by Ingold. The initial reaction appears to be an activation process of the first order. The activated form can then undergo a number of different second-order reactions with different substances. The secondary reactions compete with each other, so that the final products depend upon the concentrations and velocity constants of reactions of the substituting reagents present. Mustard gas can combine with almost all chemically reactive groups of biological systems. The differences in velocity constants of the activated molecules for reaction with different substances or groups can be expressed by means of competition factors. Thus thiophosphonates which react readily with mustard gas have high competition factors. Substances with high competition factors were tried as therapeutic agents for mustard gas poisoning, but were not very effective. The reaction of mustard gas, ββ-dichloroethyl sulphide, with water leads first to the half-hydrolysis product, β-hydroxyethyl β-chloroethyl sulphide, and then to thiodiglycol. The half-hydrolysis product has only one tenth of the toxicity of mustard gas.

Dr. J. C. Boursnell discussed the reaction of mustard gas with proteins. Early work had shown that mustard gas reacts with horse serum to give a new antigen, that it inactivates enzymes and combines with kerateine to give a product with increased chlorine and sulphur content (R. A. Peters). The free amino-groups of proteins react in alkaline solution; but other groups must also react, as the phenyl*iso*cyanate derivatives of proteins in which the amino-groups are blocked still combine with vesicants. The protein carboxyl groups also react to give alkali labile derivatives, and nutritional studies with proteins treated with mustard gas have indicated that histidine, lysine, methionine and threonine residues have reacted. Nucleoproteins react to give insoluble derivatives with high sulphur and phosphorus content (I. Berenblum and R. Schoental, *Nature*, **159**, 727; 1947). Studies with mustard gas containing radioactive sulphur (S^{35}) have shown that when the material is injected intravenously into rabbits most of the sulphur is fixed in the lungs and kidney, but pathological studies show that these organs are not seriously damaged by the vesicant.

Effects of Mustard Gas on Enzymes and Tissues

Dr. D. M. Needham described some of the work on the effect of mustard gas on enzymes and tissues. A brief account of this aspect of the subject has already appeared in *Nature* (M. Dixon and D. M. Needham, *Nature*, **158**, 432; 1946). Of a large number of enzymes subjected to the action of mustard gas in low concentrations, only the phosphokinases and some proteinases are markedly inhibited. Of the phosphokinases, hexokinase was the first to be examined, and it is probably due to inhibition of this enzyme and deuterohexokinase that the glycolysis of tissues is inhibited by vesicants. Hexokinase is a sulphydryl enzyme, but the inactivation by mustard gas appears to be due to reaction with other groups than the sulphydryl group. When hexokinase is inactivated, five or six molecules of mustard gas react with each molecule of the enzyme. Hexokinase is inhibited in the skin of animals treated with mustard gas, and this effect may be the fundamental cause of the pathological changes. Creatine phosphokinase is even more sensitive to mustard gas when tested *in vitro* but is not inhibited in tissues of animals treated with the vesicant.

British Anti-Lewisite

The development of British anti-lewisite (*B.A.L.*), which is a product of the Biochemical Laboratory at Oxford, was outlined by Dr. R. H. S. Thompson (cf. R. A. Peters, L. A. Stocken and R. H. S. Thompson, *Nature*, 156, 616; 1945). Early work carried out at Oxford (E. Walker, *Biochem. J.*, 22, 292; 1928) and in the United States showed that arsenicals reacted readily with SH groups of glutathione or of proteins. Sodium arsenite and the arsenical vesicant, lewisite, poison the pyruvic acid oxidase system of brain tissue, and the blood of animals poisoned with arsenicals has a high concentration of pyruvate analogous to that occurring in thiamine deficiency.

The pyruvic oxidase system was used as an *in vitro* test for substances which would neutralize the toxicity of arsenicals. Study of the reaction of arsenicals with kerateine showed that each atom of arsenic reacted with two SH groups of the protein. Monothiol compounds had no effect in neutralizing arsenical poisoning, but a number of dithiols were effective. Of the latter, 2 : 3-dimercaptopropanol was the most suitable, and proved to be an efficient antidote both when tested *in vitro* with the pyruvate oxidase system and *in vivo* against the vesicant action of lewisite on human skin and against the toxic action in animals and men. This compound was called 'British Anti-Lewisite' (*B.A.L.*), and it is now used clinically in treatment of arsenical dermatitis. Dr. Thompson suggested that sulphydryl enzymes might be divided into two classes: (*a*) those which are protected by monothiols, as are choline esterase and hexokinase; and (*b*) those which require dithiols, as do pyrophosphatase and pyruvate oxidase. It is possible that members of the second class require two thiol groups in close proximity for their action, whereas those of the first group need only one thiol group.

Lachrymators

Dr. M. Dixon, in describing the reactions of lachrymators with enzymes and proteins, showed how most lachrymators fall into three classes: the active ('positive') halogen compounds, unsaturated compounds and arsenicals. All lachrymators of these classes poison sulphydryl enzymes, and this suggested that the lachrymators react with sulphydryl residues. Many different experiments showed this to be the case, and the lachrymators are specific reagents for identifying sulphydryl enzymes. The active halogen-containing lachrymators can be used for the manometric estimation of sulphydryl groups as they react rapidly, giving acid proportional to the sulphydryl groups present.

Alkyl Fluorophosphonates

The alkyl fluorophosphonates are highly toxic substances, first made by Dr. B. C. Saunders and shown by Prof. E. D. Adrian and Dr. W. Feldberg and by Dr. Mackworth to be inhibitors of choline esterase. Dr. E. C. Webb discussed the nature of this inhibition, which is non-competitive and not reversed by dialysis. Eserine also inhibits choline esterase, but such inhibition is competitive (being reduced by increase in concentration of the substrate, acetylcholine) and reversible on dialysis. These new compounds are very potent. Thus horse serum choline esterase (that is, pseudo-choline esterase) is inhibited to the extent of 50 per cent by $1\cdot3 \times 10^{-9}$ *M* di*iso*propylfluorophosphonate. Such fluorophosphonates poison other esterases, such as liver esterase. In addition to the fluorophosphonates, hexaethyltetraphosphate and tetraethylpyrophosphate, which were introduced as insecticides, have been found to be extremely potent poisons of choline esterase.

'Nitrogen Mustards'

The pharmacology of the chloroethylamines, to which class the 'nitrogen mustards' belong, was described by Dr. E. Boyland. The nitrogenous vesicants, which are poly(β-chloroethyl)amines, have many properties similar to mustard gas. Study of these substances led to the discovery of interesting pharmacological properties in related compounds. Dimethyl-β-chloroethylamine, on injection into animals, causes prolonged partial paralysis, so that treated mice have the appearance of waltzing mice. Dibenzyl-β-chloroethylamine (known as 'dibenamine') antagonizes and reverses the action of adrenaline on the blood pressure. The alkyl *bis* (β-chloroethyl)-amines are very toxic substances and potent vesicants. The best known of these is methyl *bis* (β-chloroethyl)-amine (HN2). These chloroethylamines are very reactive and combine with many tissue constituents and with water to produce a series of products. One of the hydrolysis products, which has been identified as β-hydroxyethyl methyl ethyleneimonium chloride, causes partial paralysis and rapid death of mice, with convulsions. The poly(β-chloroethyl)amines are also of interest because, like mustard gas, they are radiomimetic poisons—many of their effects resemble those produced by ionizing radiations. Such effects include vesication, death following hæmoconcentration due to loss of fluid by diarrhœa and vomiting, particularly severe damage to the intestinal tract, bone marrow and lymphoid tissue, resulting in reductions in the concentrations of circulating leucocytes and platelets. Both kinds of agent have similar effects on cell nuclei, causing stickiness of nuclei and chromosome breaks. They have been shown to induce mutations in *Drosophila*, *Neurospora* and *Escherichia coli*. Both the vesicants and radioactive material cause greying of the hair of coloured mice without preventing the growth of the hair. The poly(β-chloroethyl)amines have been used clinically as alternatives to radiotherapy in the treatment of leukæmia, Hodgkin's disease and bronchogenic carcinoma. One of the drawbacks to the treatment is the nausea and vomiting caused, which are similar to radiation sickness. The similarity in effects of vesicants and radiations suggests that the study of the action of vesicants may lead to increased knowledge of the mechanism of the biological action of radiations.

At the conclusion of the symposium, Prof. R. A. Peters expressed the view that the investigations on war gases which had been started should be carried to their conclusion. He thought that biochemistry owed a debt to the Ministry of Supply, and particularly to Mr. J. Davidson Pratt and Mr. L. T. D. Williams, for their encouragement of biochemical investigations into these particular war-time projects. Much of the research has given us knowledge which is of both academic interest and practical value in peace-time.

E. BOYLAND

REPRODUCTION OF PHOTOGRAPHICALLY RECORDED OSCILLOGRAPH SIGNALS

By R. L. F. BOYD

Dept. of Mathematics, University College, London*

THE practice of recording the secular variation of an E.M.F. signal, representing some physical variable, by photographing an oscillograph screen on a moving film, is now common to almost every branch of applied science; in the past decade, many thousands of feet of film have been so used in the study of an ever-increasing variety of problems. Doubtless the versatility of the cathode ray oscilloscope is at the same time the *raison d'être* and the *sine qua non* for this ubiquity, not the least of its good qualities being its robustness and ability to continue operating under conditions which would preclude other methods.

Frequently it is required to analyse the oscillograph film record in some detail: the peak, mean, or root mean square values of the wave may be required, the Fourier components, or the value of certain ordinates and their corresponding abscissæ. Often, too, the analysis is of such a nature that it could most readily be carried out by electronic methods, as when the operation to be performed is a function of a differential operator. In view of these considerations, especially in the study of mechanical vibrations, it became evident that a means of converting the oscillograph record into an E.M.F. signal would be of value, and accordingly experiments were undertaken which resulted in the production of the curve follower described here.

The development of the instrument was both a test of the applicability of the principle employed to the general requirements enumerated above, and an attempt to meet a specialized need for a means of reproducing certain records containing frequencies from zero to about 200 c./s. Before the work was commenced, however, careful consideration was given to the possibility of employing one or other of the conventional means of acoustic reproduction (if necessary, using a frequency modulated system), such as sound-on-film or disk, or magnetic tape, and in this connexion special importance was attached to the following factors: the size and ruggedness of the recording equipment; its ability to operate in the presence of mechanical vibrations of acceleration magnitude several times that of gravity; its frequency response; and the reliability with which the original signal could be systematically and continuously reproduced. Direct reproduction from an oscillograph record offered a number of advantages: the recording apparatus is readily portable and insensitive to mechanical vibrations, consisting only of the standard laboratory type of oscilloscope and camera; and, moreover, visual observation of the signal can be carried out directly both from the record or from the tube screen. The frequency response of the reproducing equipment is constant down to D.C., a reading of the ordinate being obtained on a voltmeter plugged into the output whether the film is or is not in motion. The output-level is high without amplification (of the order of tens of volts) and is insensitive to changes in the characteristics of components or to the contrast or gradation of the film; and, moreover, it was thought that the method would be of value as an automatic curve follower for feeding analysers with any curve from which a photographic copy or other suitable black-and-white transparency could be made.

The film record, consisting of a clear line trace upon a dark ground, is mounted so as to pass between a lens and a photo-electric cell, while before the lens with its screen focused on the film is a cathode ray tube. A linear 'time-base' moves the cathode ray spot across the screen so that its image scans the film along the ordinate until it reaches the trace, at which instant the sudden change in light entering the photocell produces a pulse which is used to trigger the 'time-base', causing it to restart its sweep from the edge of the record. This process is repeated several thousand times a second, so that the mean voltage on the cathode ray tube deflector plates is a measure of the distance the spot moves from the edge of the record, that is, of the ordinate. Thus, by filtering out the time-base frequency from the sweep voltage, a signal proportional to the ordinate is obtained, and providing the frequency of variation of the signal is less than the scanning frequency by a factor greater than about 5, there is a faithful reproduction of the record.

In the initial experiments all the electronic circuits apart from the photocell were provided by a commercial type of laboratory oscilloscope (the 4-inch double-beam instrument made by Messrs. Cossor, Ltd.), the sweep voltage being produced by the oscilloscope's own 'time-base', while the amplification of the synchronizing pulse was performed by the deflexion amplifiers of the same instrument, the film being repassed through the camera that was used to make the record after it had been modified to take a photo-electric cell behind the film.

As a result of the success of these experiments and in view of the mechanical and electrical simplicity of the method, it was decided to build the instrument shown in Fig. 1, capable of reproducing continuously a loop recording carried on an aluminium drum 10 ft. in circumference. This form of construction was chosen because it completely eliminates wear on the film, and also with the view of using the instrument as the scanning part of an analyser of the type developed by Barber and his colleagues at the Admiralty Research Laboratories[1]. This analyser employs a varying width black-and-white record on photographic paper, mounted on a drum which revolves at a slowly decreasing speed. As the speed falls, each harmonic of the record is in turn brought into resonance with a vibrating galvanometer, from which a signal is obtained providing the Fourier amplitude analysis of the record. The possibility of using such an analyser directly on an oscillograph record is a considerable simplification, and at the

same time makes it possible to deal with record samples containing a harmonic range some ten times wider than was previously possible. The drum of the curve follower is the only part of the instrument which was required to be made with a high degree of precision, as any axial motion of the film would introduce a spurious signal. It would not, however, be difficult to remove the need for precision here by arranging the scan to start from some fixed line on the film, instead of some fixed voltage on the deflector plates.

The basic requirements for faithful reproduction are that there shall be an adequate rate of scan to deal with the highest frequency present in the record; that synchronization of the sweep occur reliably; that the deflexion voltage after filtering be accurately proportional to the peak deflexion voltage before filtering; and that the record be clearly defined and free from blemishes. There are two factors likely to influence the highest frequency which can be satisfactorily reproduced, assuming a record of sufficient contrast and resolution has been obtained. First, the geometry of the trace and scanning spot, as determined by the film velocity, trace thickness and electrical and optical focus of the spot must be taken into consideration; and secondly, the frequency response of the photocell and electrical circuits is important.

It is not difficult, using ordinary laboratory oscilloscopes and cameras, to produce records in which the trace is 0·005 in. wide, and a scanning spot of the same size can readily be obtained, so that it should be possible to reproduce wave-lengths on the film of 0·05 in. with an error in amplitude of about 1 per cent. Using a film speed of 18 in./sec., this would give an upper frequency limit of 360 c./s. (At the same film-speed, twice this frequency could theoretically be attained with an error in magnitude of about 12 per cent, and even this could be reduced at the cost of some slight harmonic distortion by shaping the response of the output filter.) In the present apparatus a variable film-speed up to 18 in./sec. is employed, and since, as has already been mentioned, the frequency band of interest is 0–200 c./s., there is an ample margin of response.

On considering the question of the frequency response of the electronic components, it is clear that the photocell and circuits have to deal with a pulse lasting for a small fraction of the scanning period, which itself is some ten times shorter than the period of the maximum frequency to be reproduced. This gives a pulse of about 10–15 microsec. (Fig. 2), which presents no problem so far as amplification is concerned (a straight two-stage resistance-condenser coupled amplifier is employed) but does make it necessary to give careful consideration to the photocell and cathode ray tube screen.

Let J be the luminous power from the scanning spot reaching the photocell through a clear part of the record, β the opacity of the dark part of the record, c the velocity of the scanning spot at the film, d the trace width, and T the decay constant of the oscilloscope's screen luminescence (assumed exponential). Then the change in luminous power reaching the photocell when the light spot reaches the trace is given approximately by:

$$\Delta J = \pm(1 - 1/\beta)\,\{1 - \exp(-d/cT)\}\,J,$$

the positive sign corresponding to a clear trace on a dark ground, and the negative sign to the reverse.

T is large compared with d/c, so that $\triangle J$ decreases rapidly as the scanning speed increases, and eventually becomes swamped by the shot noise from the photocell. In the early experiments a gas-filled cell was used, but the reproduction of the higher frequencies makes a hard cell more suitable, especially if it is of the electron multiplier type. If such a cell is used (as is the case here) the root mean square shot noise current is proportional to the square root of the mean cell current.

To prevent spurious synchronization of the sweep, the shot noise and hence the mean cell current (while the spot is not on the trace) must be kept at a minimum, and for this reason the transparent trace-on-a-dark-ground type of record is employed. This gives a shot noise $1/\sqrt{\beta}$ times that due to the reverse

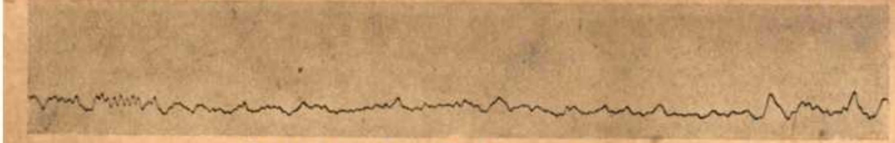

Fig. 3. CONTACT PRINT FROM SPECIMEN RECORD

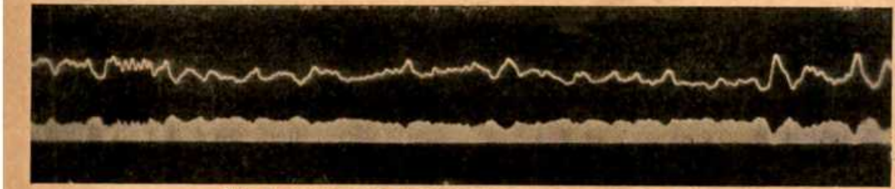

Fig. 4. ELECTRICAL REPRODUCTION OF RECORD IN FIG. 3

type, and at the same time reduces by the square of this factor noise due to modulation of the spot brilliance such as may occur if the oscillograph screen is not of uniform sensitivity. Reliable synchronization has also been assisted by thoroughly smoothing the voltage supplies to those electrodes affecting spot brilliance ; by using the first tube of the amplifier as a short time-constant electrometer and so partially integrating the pulse current ; and by introducing a small diode which rejects signals in the synchronizing circuit below a certain amplitude.

A fairly high-voltage cathode ray tube has been employed, as this gives a longer screen life than would a low-voltage tube operating at the same brilliance. The lens used with this tube is an f 1·0 coated anastigmat giving an optical reduction to 1/10.

The final output signal of the curve follower is obtained by feeding the 4 kc./s. scanning voltage through a low-pass filter preceded and terminated by cathode follower circuits, and having a cut-off at about 1 kc./s. In order that the voltage so obtained may be a faithful reproduction of the amplitude envelope of the scanning voltage, it is necessary for the latter to be linear (with respect to time) and for flyback and restart to be relatively instantaneous. For this reason O. S. Puckle's hard-valve time-base circuit[2] has been employed, the only modification being the addition of a diode to limit the flyback and so to ensure that the scan always restarts at the same voltage irrespective of the previous ordinate scanned. This was found useful in practice, though a careful setting of the time-constants of the circuits might make it unnecessary.

A microammeter reading the photocell current and a small monitoring oscilloscope have been provided to assist in setting the controls.

It will be appreciated that the absence of any requirement for a high-gain linear amplifier and the fact that the only voltage to which the output-level is sensitive is the accelerating voltage on the cathode ray tube are valuable factors, as they simplify greatly the problem of stabilization. Further, the photographic technique presents no difficulties and requires no specialized equipment, since it is only necessary to provide sufficient contrast and adequate transparency of the trace ; gradation and the actual value of the contrast being of no importance. A reversal process must, of course, be employed. At the present time Ilford 5*G*91 film is used, developed in *ID*.33 to which a small quantity of formaldehyde has been added as hardener, potassium dichromate and sulphuric acid being used for bleaching prior to redevelopment in the same developer. Initial development is carried out until there is considerable fogging, as this ensures a maximum transparency of the trace while only slightly decreasing the density of the blacks.

When the instrument is correctly adjusted, the background noise voltage, as determined by measuring the signal when the instrument was scanning a straight line trace, is about 0·5 per cent of the maximum voltage output. An idea of the performance can be gained from Figs. 3 and 4. The upper trace of Fig. 4 is an oscillograph record of the output of the curve follower when scanning the record of which Fig. 3 is a contact print. The lower trace of Fig. 4 is a record of the unfiltered scanning voltage (the phase reversal being introduced by the oscillograph used to make records).

Thanks are due to the Board of Admiralty for permission to publish this article.

OBITUARIES

Prof. Theodore D. A. Cockerell

PROF. THEODORE D. A. COCKERELL, the distinguished naturalist and moralist, died suddenly at San Diego, California, on January 26 at the age of eighty-one.

He was born on August 22, 1866, the eldest of the six children of Sydney J. Cockerell, of Beckenham, Kent ; a younger brother, now Sir Sydney Cockerell, was for many years director of the Fitzwilliam Museum, Cambridge. Threatened with tuberculosis at the age of twenty-one, he went to live in the mountains of Colorado and thrived there. Later, he held appointments at the Public Museum, Kingston, Jamaica, at the New Mexico Agricultural College, and finally back again at Colorado as professor of zoology at the University of Colorado at Boulder, where he spent the greater part of his life.

Cockerell was a keen naturalist from his earliest days, and started publishing his first observations at the age of twelve. He travelled in all the continents of the world, making collections in Hawaii, Japan, Siberia, Australia, Madeira, Morocco, the Belgian Congo, Honduras and Argentine. So recently as 1946 he flew with his wife to Honduras, intent on exploring the little-known fauna and flora of that country, and he discovered there many previously unknown animals.

He was a prolific and versatile writer on any aspect of natural history, education and ethics that crossed his path. He opened new fields for research on such subjects as snails, scale insects, fossil insects, the genetics of sunflowers, the scales of fishes, the anatomy of rodents and the classification of bees. Working early under the shadow of imminent death, he acquired the habit of hurrying his ideas and observations into print as soon as he could. The habit persisted throughout his long life, so that almost all his work appeared in the form of short papers. On the insects alone he published more than 1,200 of these. He proposed 5,500 new names for species and varieties of animals of all classes, though he worked most at the bees as he loved them the best. His collections he gave away to public museums as fast as they accumulated; 13,700 specimens of insects, many of them unique types, he gave to the British Museum (Natural History).

A final appraisal of this huge amount of work must, of course, await the verdict of future investigators. Cockerell worked easily and incessantly, and he inspired generations of American students with his quiet enthusiasm for natural history, his youthful and modern outlook, and his simple goodness; he was beloved by all who knew him.

He was twice married: first to Anne Fenn, daughter of Manville Fenn, the novelist, and afterwards to Willmatt Porter, an American devoted to the study of natural history, who survives him.

ROBERT B. BENSON

Prof. R. E. Liesegang

BY the death of Raphael Edward Liesegang on November 13, at Homburg vor der Hoehe, in his seventy-eighth year, colloid science loses one of its most cultured members.

The early years of the present century witnessed the gradual transition of interest in colloid science from its qualitative and descriptive to its quantitative and mathematical aspects. A few notable workers, now a rapidly diminishing number, made their contributions over this period of transition. Among these, R. E. Liesegang must be regarded as one of the most important. Temperamentally, he was endowed with a high artistic sense, and both his command of languages and the purity of his prose were attributes which played an important part in his scientific work.

His name will always be associated with that interesting phenomenon of periodic precipitation in gels, resulting in the formation of 'Liesegang rings'. The beautiful structures in banded agates can readily be reproduced in the laboratory by diffusion of electrolytes into gels containing suitable precipitants. Many claims resting, however, on somewhat more slender experimental evidence have also been made to interpret several different types of lamellar structures in biological material in terms of Liesegang precipitation.

Liesegang made notable contributions to our knowledge of the sensitiveness of photographic emulsions to light, and must be regarded as one of the pioneers in the fields of colour photography and television. Investigators interested in the early development of methods owe a great debt to Liesegang for his "Kolloidchemische Technologie". ERIC K. RIDEAL

WE regret to announce the following deaths:

Dr. C. W. Kimmins, for many years chief inspector of the Education Department of the London County Council, on January 12, aged ninety-one.

Prof. Burton E. Livingston, emeritus professor of plant physiology, Johns Hopkins University, aged seventy-two.

NEWS and VIEWS

British Hydromechanics Research Association

THE design and manufacture of hydraulic machinery is one of the oldest and most important branches of mechanical engineering, including, as it does, water turbines for power production, pumps of all kinds for water and other liquids, hydraulic presses for various purposes and a great variety of other machines and equipment associated with nearly all forms of industrial activity. At the present time, British manufacturers of such machinery are making a full and valuable contribution to the export drive. But the industry is a competitive one, and it is welcome news that despite their present preoccupations, the leading manufacturers have realized that it is only by continuous co-operative research and development that these activities can be maintained and extended, and have formed the British Hydromechanics Research Association for this purpose. The president of the Association is Sir John Anderson, and it is a good sign that the Council, in addition to representatives of the leading manufacturers, includes representatives of large users of hydraulic machinery.

The director of the new Association will be Mr. L. E. Prosser, who has had many years experience of research in basic and applied fluid mechanics at the National Physical Laboratory, and of the application of the results of such researches to the solution of important problems encountered in engineering practice. The Association will work in close co-operation with the new Mechanical Engineering Research Organisation of the Department of Scientific and Industrial Research, which is planning to erect a well-equipped hydraulic machinery research laboratory as one of its most important activities in the general development of mechanical engineering science and its application to useful purposes. It has been said with some justification that whereas Great Britain has taken a leading part in the development and application of research in aerodynamics, the sister science of hydromechanics has been neglected. These new activities should go a long way to remedy this discrepancy, with resulting advantages both to manufacturers and to users of hydraulic machinery.

Research in Central Africa: Dr. J. E. Keyston

SUPPORT was forthcoming from all branches of scientific opinion for proposals put forward in 1946 at the Royal Society Empire Scientific Conference that research in Africa, south of the equator, should be planned and organised on a regional basis. Even before the Conference, the three Central African territories of Southern Rhodesia, Northern Rhodesia and Nyasaland were contemplating arrangements for a joint attack upon the research problems of their own sub-region of Africa, and for collaboration with the research organisations in the neighbouring territories of East Africa and the Union of South Africa. The Central African Council, which is a consultative assembly of representatives of the three Central African countries, has given effect to proposals made by a Special Committee on Joint Research set up at the end of 1945, by appointing a 'research secretary' whose first duty will be to survey the research facilities available in the Central African, East African and South African territories, to report on any additional facilities required in Central Africa and on the relations to be established between research work and workers in Central Africa and in other countries. This survey is expected to lead to recommendations regarding the nature, priority and future organisation of research in Central Africa.

Dr. J. E. Keyston, who arrived at Salisbury, Southern Rhodesia, in November 1947 to take up the appointment of research secretary, graduated with first-class honours in physics at University College, Nottingham, and thereafter pursued research on gas discharges and on the hyperfine structure of spectral lines at Nottingham, the Electrical Laboratory, Oxford, and the Einstein Laboratory, Potsdam. During 1933–37 he held a scientific appointment in industry and then joined the staff of the Admiralty Research Laboratory. Since the end of 1938 Dr. Keyston has served in the Admiralty headquarters department of scientific research, where he became assistant director of scientific research in 1943 and later deputy director of research programmes and planning. His wide experience of research administration and, in particular, his record in promoting close and friendly liaison between the Admiralty and other research bodies, including the research organisations of the Dominions and the United States, appear well matched to the duties he is to undertake for Central African research.

Beilby Memorial Awards

AWARDS are made annually from the Sir George Beilby Memorial Fund to British investigators in science as a mark of appreciation of distinguished work, particularly in such fields as fuel economy, chemical engineering and metallurgy, in which Sir George Beilby's special interests lay, and generally as an encouragement to younger men. Owing to the War, no awards were made during 1941–46 inclusive; but at a recent meeting of the administrators it was decided to make awards for 1947 to Dr. G. V. Raynor, for his researches on the constitution of alloy systems; and to Dr. G. R. Rigby, for his researches on refractory materials.

Dr. G. V. Raynor was educated at Nottingham High School and Keble College, Oxford. He obtained a first-class in the Honours School of Natural Science (Chemistry) in 1936 and, after a year of postgraduate research on copper alloys in the Inorganic Chemistry Laboratory of the University of Oxford under Dr. W. Hume-Rothery, became research assistant to the latter for work on factors affecting the formation of magnesium alloys. Following election to a senior research award of the Department of Scientific and Industrial Research, he continued investigations on magnesium alloys and obtained the degree of D.Phil. in 1939. During the war period Dr. Raynor was concerned, in association with Dr. Hume-Rothery and others, with work on the constitution of certain steels and aluminium alloys on behalf of the Service Ministries. Early in 1945 he entered the Metallurgy Department of the University of Birmingham as research fellow and became reader in theoretical metallurgy two years later. His work in Birmingham has been directed towards a better understanding of the theory of alloy formation, with particular reference to the behaviour of the transitional metals, and the factors governing equilibrium relations in ternary alloys.

Dr. G. R. Rigby was born at Stoke-on-Trent and, after receiving his general education at Hanley High School, studied chemistry at the North Staffordshire Technical College. In 1928 he was awarded a Royal Scholarship and proceeded to the Imperial College of Science and Technology, London, where he obtained two years later the A.R.C.Sc. diploma and the B.Sc. degree of the University of London with first-class honours. He spent the next two years in the Physical Chemistry Department of the College engaged in research under the late Prof. J. C. Philip on the measurement of electrical charges at gas–liquid interfaces, and was awarded the Ph.D. degree for a thesis on this subject. His appointment in 1932 to the staff of the British Refractories Research Association brought him into touch again with the Staffordshire pottery industry. Initially under the direction of the late Dr. J. W. Mellor and, since 1937, of Mr. A. T. Green, Dr. Rigby has been engaged continuously on a wide range of research work on refractory materials for the pottery industry, and latterly for the iron and steel industry.

Road Research

FOR three months during 1946, Dr. W. H. Glanville, director of the Road Research Laboratory of the Department of Scientific and Industrial Research, visited North America to study the progress made there in applying the results of research to road construction and safety. A report of the visit has now been published as "Road Research Technical Paper No. 7" (London: H.M. Stationery Office, 1947. 1*s.* 6*d.* net). The Road Research Laboratory was engaged in important work during the War, which necessarily hindered the development of the programme of road research in Britain, particularly as regards road safety and the construction of concrete roads. The main purpose of the American visit was to see the progress made in these directions. Problems relating to the serious matter of road safety are being actively investigated in many parts of the United States. As in Britain, the problem is being tackled under three main headings: education, engineering and enforcement. It is interesting to note that while improvements in vehicles in aspects concerning safety are largely in the hands of the motor industry, concerted action is being taken, and the Automobile Manufacturers Association has formed an Engineering Liaison Committee which, by the pooling of patents and ideas, has produced a standard headlamp now fitted to all new American cars. The Committee is also at work on the problem of dazzle, which with the imposition of a partial black-out in towns in Britain has taken on a new urgency. Successful tests have been carried out by the General Electric Co. on the use of headlights emitting polarized beams; with the use of a 'Polaroid' visor it is possible to pass a car with its headlights full on with no discomfort although the road around appears well illuminated. The technical problem appears to be solved; but the difficulties associated with transition from plain to polarized lights remain. In America, as in Great Britain, the design of the structure of the carriageway is based more on the result of experience than on scientific principles. However, much experimental work is in hand which will enable theories to be tested. As an appendix to the report, extracts are given from the programme of the Highway Safety Conference held in Washington, May 1946.

Survey of Svalbard

The Norwegian Svalbard department (Norges Svalbard-og-Ishavs-undersökelser), as can be judged from the report of its activities 1936–44 (*Skrifter*, Nr. 88. Oslo: Jacob Dybwad, 1945. 6.50 kr.), was busy during the period of enemy occupation, although the last expedition to Svalbard was in 1939 and to East Greenland in 1941. The report contains full accounts of these expeditions and of the useful work done in Oslo in compiling various Svalbard maps, on the bibliography of Norwegian polar literature and the exhaustive report on Svalbard place names. "The Survey of Björnöya" (Bear Island), completed between 1922 and 1931, forms a separate publication with full details of the work and a revised edition of the contoured map of the island on a scale of 1 to 25,000. This is printed in brown, blue and black. Small reproductions of some of the earlier sketch maps of the island are also given. This monograph, together with that of G. Horn and A. K. Orvin on the geology and history of the island (*Skrifter*, Nr. 15. Oslo, 1928) with its geological map, form an exhaustive survey of the island, which is now one of the most carefully surveyed areas in polar regions.

Svalbard includes all the islands over which Norway acquired sovereignty by the treaty of 1920. These islands lie between lat. 74° and 81° N., and long. 10° and 35° E. Included are Spitsbergen, Bjørnøya, Hopen, Kong Karls Land and Kvitøya. The Svalbard Archipelago has been visited by western Europeans since A.D. 1194, and it is generally agreed that the Svalbard mentioned in the Icelandic annals refers to these islands. In 1596 the Dutch arrived while trying to discover the North-East Passage, and from the start of the seventeenth century there was much Dutch and English whaling activity. From about 1720–1852, Russian trappers used to winter there and have left traces of their visits. Since then there have been not a few purely scientific expeditions to the region. A list of place names has now been issued (Skrifter om Svalbard og Ishavet, Nr. 80. Pp. 540. Oslo: Jacob Dybwad, 1942. 50 kr.). The names are arranged alphabetically, and bibliography, indexes and a map are included. The committee responsible is to be congratulated on a notable piece of work. It is written in English.

Carnegie United Kingdom Trust

The thirty-third annual report of the Carnegie United Kingdom Trust, to which are appended the accounts for the year ending December 31, 1946, records the progress made during the first year's execution of the plans for the current quinquennium. The principal allocations for the quinquennium opening on January 1, 1946, are £150,000 for music and drama; £100,000 for village halls; £150,000 for the Bureau of Current Affairs; £30,000 for museum services; £25,000 for Young Farmers' Clubs, and £40,000 for youth hostels. The Trust is constituting a small committee to examine the recommendation in Miss E. Younghusband's report on the training of social workers, for the establishment, in association with an appropriate university, of a Carnegie School of Social Work. A new grant has been promised to the National Federation of Women's Institutes in aid of the foundation of a residential centre, at Marcham Park, near Abingdon, to which countrywomen may resort to study problems affecting rural life and for suitable courses of instruction. A grant up to £750 has been promised to enable the Central Landowners' Association, together with other bodies concerned with the preservation of the countryside, to promote a competition designed to encourage the study of village planning.

Funds are being made immediately available for museum services for three main purposes: the supply of expert reports to museums which may wish to consider possible lines of development; the provision of grants to museums already able to carry out approved schemes of reorganisation; and the training of museum staffs. The Trust has continued to meet the whole cost of maintaining the Irish and Scottish Central Libraries for Students, and, in addition to renewing its grant in aid of the National Central Library, has made exceptional grants of £400 to Rutland and £1,500 to Argyll for the establishment of a county library service. A further grant of £6,000 has been promised to the Council for the Promotion of Field Studies for the adaptation and equipment of Flatford Mill, as a pioneer field centre. Grants of £2,500 to the Highland and Islands Film Guild for the provision of a mobile film service in two of the crofting counties of Scotland, a capital grant of £2,500 for the adaptation and equipment of Bisham Abbey as a national recreation centre by the Central Council of Physical Recreation, and a grant of up to £1,000 a year for five years for an inquiry into certain aspects of juvenile delinquency to be conducted at the Philanthropic Society's School, Redhill, are also recorded.

Earthquake in the Philippines

On January 25, a series of some eleven earthquake shocks shook the central Philippine Islands for about four hours. The sugar-growing island of Panay, approximately 285 miles south-west of Manila, was most affected, and the islands of Negros, Cebu, Leyte and Marinduque, all densely populated, were also shaken. The six-storied campanile of the ancient Jaro cathedral collapsed and some fissures caused by the earthquake were more than 100 yards long. Altogether damage was caused to the extent of about £100,000, and at least twenty-seven deaths and many injuries were occasioned by the shock. The earthquake was recorded at observatories throughout the world as the greatest since the Japanese earthquake of December 21, 1946.

The Philippine Islands are definitely in a seismic zone, small shocks occurring there frequently. Considerable earthquakes are reported from time to time, and an extensive catalogue of these, from the Manila earthquake of 1589 to the Butuan earthquake of December 26, 1899, has been compiled by the Rev. William C. Repetti, *S.J.* Destructive earthquakes occurred at Batangas on December 14, 1901, and in the centre of Mindanas on August 21, 1902. Lehmann and Plett wrote an interesting paper on the Philippine earthquake of November 13, 1925.

International Congress of Applied Mechanics

The Seventh International Congress of Applied Mechanics will be held at the Imperial College of Science and Technology, South Kensington, London, during September 5–11. The technical sessions will be organised under the following sections: (1) Elasticity and Plasticity; (2) Aerodynamics, Hydrodynamics, Meteorology; (3) Thermodynamics, Heat Transfer, etc.; and (4) Vibrations, Lubrication and Experimental Methods. In addition, as many as ten general lectures or surveys are contemplated on subjects likely to be of interest to members. Arrangements have been made for visits to the National Physical Laboratory, the Royal Aircraft Establishment, the National Gas Turbine Establishment, and the Research Laboratories of the General Electric Co., Ltd., during the week following the Congress. Forms of application for membership, and other material concerning the Congress, can be obtained from the Organising Secretary, Seventh International Congress of Applied Mechanics, Imperial College of Science and Technology, London, S.W.7.

Theories of Creep in Metals

A SUMMER school in theoretical physics, with particular application to creep in metals, will be held in the H. H. Wills Physical Laboratory of the University of Bristol during June 2–5. The course is intended mainly for members of the staffs of Government and industrial laboratories who wish to familiarize themselves with the theoretical side of subjects with which they have been concerned on the experimental side. Lectures will be given by Prof. N. F. Mott and other members of the staff of the H. H. Wills Physical Laboratory. In addition to the regular lectures, there will be opportunities for research workers attending the course to discuss their own work and its theoretical implications. Subjects to be treated will include: anelastic effects due to slip at grain boundaries; grain growth, recrystallization and the theory of grain boundary slip; geometry of dislocation and the theory of slip bands; theory of transient creep; slip in solid solutions; diffusion of carbon in iron and elastic after-effect; effects of carbon on the mechanical properties of iron; mechanisms of internal damping; crystal growth and the origin of dislocations. The number attending the course will be limited to about fifty, and the fee for attendance 5 guineas. Further particulars and forms of application, to be returned by April 15, can be obtained either from the Director of the Department of Adult Education, University of Bristol, or from the Secretary of the Institute of Physics, 47 Belgrave Square, London, S.W.1.

The University of Bristol, in co-operation with the Institute of Physics, announces also a second summer school in the physics of solids (experimental and theoretical) to take place in Bristol during September 8–15, the subject being "The Oxides and Ionic Crystals". Further details will be announced in due course.

University of London

DR. LESLIE YOUNG, reader in biochemistry in University College, London, and formerly professor of biochemistry in the University of Toronto, has been appointed to the university chair of biochemistry tenable at St. Thomas's Hospital Medical School as from April 1.

The degree of D.Sc. has been conferred on: Mr. W. S. Rogers (East Malling Research Station); Dr. B. N. Singh (Rothamsted Experimental Station); Mr. F. L. Warren (Royal Cancer Hospital (Free)).

Industrial Research in Wales

A REGIONAL conference on "Industry and Research in Wales", organised jointly by the Industrial Research Committee of the Federation of British Industries and the Industrial Association of Wales and Monmouthshire, will be held at Cardiff on March 10. Sir William Griffiths, managing director of the Mond Nickel Co., Ltd., will preside at the morning session and Sir Gerald Bruce, of the Industrial Association of Wales and Monmouthshire, in the afternoon. Among others taking part will be Sir Frederick Rees, principal of University College, Cardiff, Dr. W. D. Scott, of Monsanto Chemicals, Ltd., Capt. H. Leighton Davies, of the Steel Company of Wales, Ltd., Mr. Harry Davies, of I.C.I., Ltd., Dr. Idris Jones, of the National Coal Board, and Mr. R. K. Sanders, of the Metal Box Co., Ltd. Sir Percy Thomas, of the Welsh Board for Industry and the Industrial Association of Wales and Monmouthshire, will sum up. Further particulars can be obtained from the Industrial Research Secretariat, F.B.I., 21 Tothill Street, London, S.W.1, or from the Industrial Association of Wales and Monmouthshire, Aberdare House, Mountstuart Square, Cardiff.

Convention on Scientific Radio

A CONVENTION on Scientific Radio is to be held during April 7 and 8 by the Institution of Electrical Engineers and the British National Committee for Scientific Radio (set up under the auspices of the Royal Society), and is being organised by the Radio Section of the Institution. This is intended to serve as a preliminary survey of the British contribution in the radio field which is to be presented at the forthcoming meeting of the Union Radio Scientifique Internationale to be held in August 1948 in Stockholm. The Convention is divided into four sessions, corresponding in scope to those of the International Union, covering (1) standards and measurements; (2) propagation; (3) radio noise; and (4) radio physics.

Announcements

GENERAL SMUTS has been elected chancellor of the University of Cambridge in succession to the late Lord Baldwin.

DR. HAROLD SCARBOROUGH has been appointed lecturer with title of reader in the Department of Medicine, University of Birmingham.

THE Langley Memorial Prize, value £21, is open to competition among officers of the Colonial medical service who are serving, or who have served, in West Africa. The prize will be awarded for the best paper submitted on a topic falling within one of the following subjects (special consideration being given to original work): (*a*) tropical medicine or surgery; (*b*) tropical hygiene and sanitation; (*c*) tropical entomology and parasitology. Papers, which may consist of either published or unpublished work, should be delivered to the Assistant Dean, London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1, not later than October 1, 1948.

THE trustees of the Lady Tata Memorial Fund invite applications for grants and scholarships, open to workers of any nationality, for research in diseases of the blood, with special reference to leukæmia, in the academic year beginning on October 1, 1948. Grants are made for research expenses or to provide scientific assistants to senior workers; scholarships (£400 per annum for whole-time research) are awarded as personal remuneration. Forms of application, to be returned before March 31, can be obtained by writing to the secretary of the Scientific Advisory Committee, Lady Tata Memorial Trust, c/o Medical Research Council, 38 Old Queen Street, Westminster, London, S.W.1.

A Short-Focus Modification of the Lamm Scale Method for Measuring Refractive Index Gradients

THE scale method is still regarded as the most accurate and reliable method for measuring refractive index gradients and is extensively used in diffusion and sedimentation measurements. The considerable laboratory space required by the long cameras is, however, inconvenient. I have studied the problem of the necessary focal length in detail, and come to the conclusion that the long focal length is not essential for the method.

Lamm[1] has given a number of reasons for using an objective with a great focal distance. It seems that several of these arguments are questionable. One requirement is essential, however, namely, the use of parallel or nearly parallel light through the cell. It was pointed out by Lamm himself (*loc. cit.*, p. 9) that it should be possible to attain this condition by placing the diaphragm in the focal plane of the objective, which could then have a much shorter focal length. This proposal has now been taken up for further study.

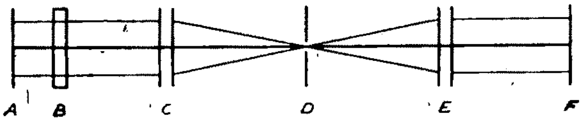
A camera giving an image of natural size with a diaphragm in the focal plane of the objective is not suitable, because a lens cannot be corrected for two purposes so widely different as giving exactly parallel light from the focal point and giving a good image of natural size. The former requirement is fulfilled by an asymmetrical astronomical objective, the latter necessitates a symmetrical lens system; to unite these two requirements, a compromise must be made in the correction of the lens, and a long focal-length may still be necessary.

It is not possible to solve this problem without introducing two lenses. An astronomical objective may be placed near the cell, and the diaphragm in its focal plane. A second lens can give a full-size image of the scale.

There are special advantages in placing the second lens at the focal distance from the diaphragm. In such a case the light is parallel on both sides of the lens system. In this arrangement both lenses should be of the simple astronomical type. From elementary optics it is known that a lens system of two lenses with a common focal plane has its principal planes infinitely far away; thus the magnification depends only on the two focal distances and not on the mutual distances between object, lens system and image. Needless to say, this latter property is of special advantage in the scale method, where the scale position in relation to the camera has to be altered several times during an experiment. If a confocal lens system is used, the magnification remains unaltered.

The magnification is equal to the ratio between the two focal distances. Since there is no reason for magnifying or reducing the scale image, I use two identical astronomical objectives in the camera. Two more advantages are gained by this: the magnification becomes exactly 1, which is very convenient, and the total length from the scale to its image is independent of the scale distance (the optical distance between scale and cell). Thus, if the scale distance is increased by 100 mm., the plate has to be moved 100 mm. in the same direction to restore the focusing, and the magnification of unity is unaltered.

In the original scale method, a correction factor $(l - b)/l$ (l is the distance between scale and lens, b is the scale distance) must be used to calculate the cell co-ordinate from the scale co-ordinate. In the new modification, this factor is also equal to unity, since the light travelling between the scale and the cell must be parallel. Thus the new modification simplifies the calculations considerably.



A, scale; *B*, cell; *C*, astronomical objective $f = 50$ cm.; *D*, diaphragm; *E*, astronomical objective $f = 50$ cm.; *F*, plate

A diagram of the new scale camera is reproduced herewith. It has been tested in diffusion measurements in this Institute for a couple of months and has given results indistinguishable from those obtained with the original method. Experiments will be continued to test the camera in connexion with ultracentrifugal and equilibrium centrifuge measurements.

The distance between scale and plate in our diffusion apparatus was 4 m. with the original scale method. It has now been reduced to 2 m. The corresponding distance in the ultracentrifuges and equilibrium centrifuges is 6 m.; thus 4 m. can be saved, and still more, since the centrifuge cells are considerably smaller than the diffusion cells. The focal length of the lenses can be reduced according to the size of the cell.

I wish to express my gratitude to Prof. Ole Lamm for the kind interest he has devoted to this work and for helpful discussions. I am also indebted to LKB-Produkter Fabriks-AB, Stockholm, for financial support.

Sensitivity of a South American Frog to Curare

FROM time to time, reports have appeared of the low sensitivity of South American frogs to curare[1,2].

These early experiments were made with crude curares, the reliability of which is always doubtful and in which apparent differences in potency may be due to differences in, for example, absorption-rate, produced by substances other than the curare alkaloids. We recently have had an opportunity of testing the sensitivity of *Leptodactylus ocellatus* to *d*-tubocurarine chloride supplied to us by Dr. Harold King, of the National Institute for Medical Research, Hampstead, London, N.W.3.

The tests were made at room temperature (21–24° C.) on frogs weighing between 25 and 70 gm., and the technique was the same as that described by King[3].

The *d*-tubocurarine chloride was dissolved in Ringer's solution and injected into the ventral lymph sac of the frogs in a volume of 0·02 c.c. per gm. of frog. The same end-point was used, namely, inability of the frog to recover its normal posture when placed on its back.

Preliminary experiments on six frogs showed that doses up to 10 mgm./kgm. were without any visible effect. Of three frogs which received 15 mgm./kgm., one only became paralysed after 67 min. had elapsed. With doses of 20–30 mgm., paralysis developed in all frogs, but only after 19–50 min. A dose of 40 mgm./kgm. in three frogs produced paralysis in 18, 26 and 28 min.

Since the test described by King required paralysis to occur within 15 min., the dose was increased to 50 mgm./kgm., and this quantity was administered to six frogs. In these, paralysis developed in 13, 14, 14, 14, 15 and 16 min.

King[4] stated that for frogs the paralysing dose of *d*-tubocurarine chloride was 0·5 mgm./kgm. There appears to be no doubt that *Leptodactylus ocellatus* is considerably less sensitive to the alkaloid than is the *Rana temporaria* used for the original tests, a finding which confirms that of Houssay and Hug[2].

The comparison which we have made is, of course, unsatisfactory in many ways; but the experiments were limited by the supply of curarine immediately available. It is hoped in the near future to make comparisons simultaneously on the two amphibians under identical conditions.

This relative insensitivity of *Leptodactylus ocellatus* to substances affecting neuromuscular transmission does not seem to be confined to *d*-tubocurarine chloride, since we have recently found that this frog is less sensitive to acetylcholine than is *Rana esculenta*[5], although the difference is much less striking than in the instance of *d*-tubocurarine chloride. We have also found a similar insensitivity of these frogs to atropine injected arterially into the gastrocnemius muscle. In *Rana esculenta* one injection of 100 μgm. in 0·1 c.c. rapidly produced complete neuromuscular block[6]. In *Leptodactylus ocellatus* three successive injections of 200 μgm. in 0·2 c.c. only reduced the twitch tension to about a third of its original value.

Sodium Citrate Concentration in Ether-extracted Plasma

A method has been described for the fractionation of human plasma in which fibrinogen is precipitated by ether, and prothrombin by adjusting the *p*H of the supernatant to 5·3 with 0·2 *M* citric acid[1]. The plasma remaining is frozen with excess of ether and the protein concentrated for use as a transfusion fluid[2]. We would like to direct attention to the fact that such solutions of proteins from citrated plasma may contain a dangerously high citrate concentration.

A transfusion reaction reported after the use of material prepared by the above method led us to examine the effects of its injection into rabbits, in which the injection of fluid or reconstituted dried pooled human plasma, where the protein is not concentrated, causes no disturbance of blood pressure or respiration.

When 5 ml. of the plasma used in the transfusion were injected into rabbits anæsthetized with 'Nembutal', there was an immediate fall in blood pressure, slowing of the heart-rate, an immediate acceleration of respiration succeeded by deep convulsive gasps or cessation of respiration and twitching movements of the musculature. Recovery usually occurred in a few minutes.

Dialysis of the plasma against distilled water using a collodion membrane removed the active factor. This, and the effects observed in the rabbit, suggested that the toxicity was due to citrate.

Estimation of citrate by the method of Pucher, Sherman and Vicary[3] showed the citrate concentration in pooled plasma to be about 11 mgm./c.c., in ether-extracted plasma about 15 mgm./c.c., and in plasmas prepared from fractionation residues to vary from 16·7 mgm./c.c. to 23·0 mgm./c.c. The injection of 5 ml. of ether-extracted plasma containing 22·5 mgm. citrate per c.c. produced the same effects in the anæsthetized rabbit as those caused by the injection of the plasma which produced the transfusion reaction. Injection of a similar quantity into unanæsthetized rabbits caused tetanic convulsions and opisthotonus. These effects could be reproduced by a citrate solution of the same strength. Dialysis of the plasma or the previous injection of calcium chloride prevented these effects; and injection of the dialysate, concentrated to the original plasma volume, showed that it contained the active agent, the effects of which were annulled by the previous injection of calcium chloride.

The manifestation of the toxic effects of citrate depends both upon the rate of injection and the concentration of citrate in the injected material. Since transfusions in certain conditions may be given very rapidly, we consider that the possibility that ether-extracted plasma prepared by the method of Kekwick, Mackay and Record[1] may contain a high concentration of citrate, which might under certain conditions prove toxic, should be made known.

Effect of Antihistamines on *Daphnia*

Daphnia pulex reacts under ultra-violet radiation (wave-lengths less than 4000 A.) with negative phototaxis. In man the influence of the same wave-lengths is connected with release of histamine from damaged cells[1]. Successful therapy with antihistamine in cases of human hypersensitivity to sunlight is therefore not surprising[2]. The working hypothesis which we used was as follows : it is possible that the release of histamine occurs in both cases. If this assumption is correct, antihistamine should modify the motor response of *Daphnia* (phototaxis) in the same way as it prevents the actinic dermal response in man subjected to sunshine.

As light source we used a low-pressure mercury vapour lamp. We tested typical antihistamine substances of well-known activity. They were: α-benzhydrylether-β-piperidinoethane (I)[3], antihistamine activity tested on guinea pig intestine: 6·3 microgm.; 2-phenylbenzylaminoethyl-imidazolin (II) (Antistin-Ciba), 45 microgm.; α-phenylamino-β-aminoethane (III)[4], 29 mgm. It was found that all these substances in small doses suppress the negative phototaxis of *Daphnia*; in larger doses, they invert the phototaxis to positive. This influence is proportional to the concentration of antihistamine used. The minimal effective dose for the substance I is 2·5 microgm. per c.c. of medium (M/133,000).

This reaction seems to be a specific one; it was not possible to provoke it with organic acids (acetic, lactic), lactose, glycocol and sodium choleinicum. Only strychnine among organic substances shows the same influence as antihistamines[1] on *Daphnia*[5]. The mechanism of its action is clearly neurotropic. Further, it was found that the ratio of activity of three antihistamine substances in this *Daphnia* test was the same as in the test on the surviving intestine of the guinea pig. Therefore, it cannot be excluded that the actinic influence of ultra-violet light provokes the release of histamine in invertebrates as in man, although histamine itself, when added to the medium, did not influence *Daphnia* in any way.

Histaminolytic Activity of a Copper Protein in Serum

WE have recently been studying the blue serum globulin described by Luetscher[1], Pedersen[2], Holmberg[3] and Cohn *et al.*[4].. We have found that it has a copper content of about 0·05 per cent. By denaturing with a mixture of ethyl alcohol and chloroform and fractionating the supernatant solution with ammonium sulphate, we have found a blue copper protein with a copper content of 0·36 per cent. It seems very probable that this substance is identical with the hæmocuprein of Mann and Keilin[5], which thus might be an integral part of the blue globulin.

When a purified preparation of this globulin was added to plasma from a male subject so that the final copper concentration was about 700 γ/100 ml., the result was a 400-fold increase in histaminolytic activity. The blue globulin thus seems to be a component of the histaminolytic enzyme system of plasma.

As is well known, the increase in serum copper during pregnancy runs parallel in time with the increase in histaminolytic activity of plasma. We have also shown that this increase in copper is to be found in the globulin fraction of plasma.

A more detailed report of these investigations will soon appear in the *Acta Chemica Scandinavica*.

Our thanks are due to the Obstetrical Clinic of the Hospital of Malmö for help with the determinations of the histaminolytical activity of our preparations.

Specific and Non-specific Competition in Tubular Excretion

A CONSIDERABLE number of aromatic acids are known to be excreted by the renal tubules. The chemical structure of these compounds shows much variety, and it does not seem easy to find any property common to them which is not also shared by substances not excreted by the tubules. However, in every case hitherto investigated, the tubular excretion of any anion is reversibly depressed by the presence of considerable amounts of other anions excreted by the tubules. This effect is usually demonstrated by the use of 'Diodrast' or hippuric acid as the depressing agent. The phenomenon is often regarded as an indication that the excretion of these compounds is effected by a common mechanism, or by intimately linked mechanisms.

It has, however, in some cases been shown that the presence of large amounts of 'Diodrast' in the blood may also interfere with reabsorptive processes in the tubules. This circumstance has led to the division of the effects of 'Diodrast' into specific and non-specific competition[1].

It seems clear that the depression of tubular excretion by 'Diodrast' may be non-specific, as well as its effect on tubular reabsorption. Thus the foundation for the view that the excretion of anions by the tubules is determined by specific interaction is considerably weakened by the demonstration of non-specific competition. In order to gain some further information as to the specificity of the depression of tubular excretion, the influence of hippuric acid on the excretion of uric acid has been studied in the chicken.

The intravenous injection of 100–200 mgm. hippuric acid causes the uric acid excretion in a hen to fall by 20–50 per cent for a short period (about ten minutes). Afterwards the uric acid excretion rises slightly above the original level for some time, but soon returns to it. This effect might be interpreted as the result of a diminution of the renal blood flow, possibly caused by the hippuric acid. However, the excretion of piperidine, which is also excreted by the tubules in the chicken, is not influenced in a consistent manner. This is evidence against an influence on the blood flow.

Similarly, the excretion of phenol red is depressed by the intravenous injection of uric acid. In this case the excretion of methylnicotinamide has been used to assess the constancy of the renal blood flow, which seems to be constant or slightly increased.

In man, uric acid is reabsorbed by the tubules; the reabsorption is depressed by 'Diodrast'[2]. It is thus clear that the depression by hippuric acid (or 'Diodrast') cannot be regarded as demonstrating excretion by a common mechanism. Though there is no doubt about the existence of both specific and non-specific competition, it seems that we are at present unable to distinguish between these two phenomena.

Improved Method of Getting Rats' Eggs from the Fallopian Tubes

Rowlands[1] described the recovery of rats' eggs by unravelling the Fallopian tubes and squeezing out their contents under low-power magnification. Using this method he obtained an average of 4·9 ± 0·5 (standard error of the mean) ova per rat from the tubes of thirteen normal rats two days after mating[2]. Using the same method in forty rats killed 0–2 days after mating, we recovered a similar number of eggs (4·2 ± 0·3 per rat).

A significantly higher average recovery was obtained when the ova were washed out of the Fallopian tubes. A blunted hypodermic needle (26 wire gauge) can easily be inserted into the open ovarian end of the unravelled tube (or into an oblique slit made just below it) and the ova washed out with five to ten drops of physiological saline from a 1-ml. syringe. The washing method is only preferable when the eggs are no longer clumped together surrounded by cumulus cells but are scattered free throughout the length of the tube—that is, more than 24 hr. after mating. Before this time the original method is the better one. By the modified technique the average number of eggs recovered from thirty-six rats 0–2 days after mating was 7·8 ± 0·4 eggs per rat, a number more in keeping with the normal litter size.

This work was initiated when one of us (P. C. W.) was Prophit Research Student of the Royal College of Surgeons, and it was aided by an apparatus grant from the University of London.

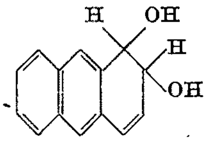
Oxidation of Anthracene by Osmium Tetroxide

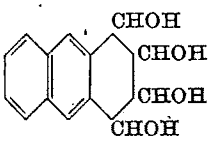
We have shown recently[1] that the addition of osmium tetroxide to the 9 : 10-positions of phenanthrene, first observed by Criegee, Marchand and Wannowius[2], is a general property in a series of tetra- and penta-cyclic aromatic hydrocarbons containing a phenanthrene system. If the reaction is carried out in the presence of pyridine a well-crystallized, deep-coloured, pyridine-osmic ester complex is formed, and this on hydrolysis gives a dihydroxy-dihydro derivative of the original hydrocarbon.

The presence of a phenanthrene system is not essential, for anthracene and naphthalene form similar coloured complexes. If, in the case of anthracene, the reaction could be limited to addition of osmium tetroxide to *one* aromatic double bond, then it is probable that hydrolysis would give *dl-cis*-1 : 2-dihydroanthracene-1 : 2-diol (I), which Boyland and Shoppee[3] have shown to be the metabolic oxidation product of anthracene in rabbits. Whether the reaction could, in fact, be so limited seemed very doubtful as addition of osmium tetroxide to anthracene takes place slowly, and the product of addition of one molecule of the tetroxide would contain a true ethylenic linkage which should react rapidly with a second molecule of osmium tetroxide with formation of an osmic ester complex of a tetrol.

This conclusion has been verified experimentally, for hydrolysis of the anthracene-osmium tetroxide-pyridine complex gave a tetrahydroxytetrahydroanthracene. If the above reasoning is sound, this should be the 1 : 2 : 3 : 4-tetrahydro compound. That this is indeed the case was supported by a measurement of the ultra-violet absorption spectrum by Mr. E. J. Y. Scott, who found $\log \varepsilon = 5{\cdot}25$ at 2330 A. for a methanolic solution of the tetrol (2·34 mgm. in 500 ml.). This suggests a naphthalene derivative (II), and final confirmation of this was provided by oxidation of the tetrol by alkaline potassium ferricyanide solution to naphthalene-2 : 3-dicarboxylic acid, m.p. 238–239° alone or mixed with a sample prepared by similar oxidation of 2 : 3-dimethylnaphthalene. It is noteworthy that the very reactive *meso* positions of anthracene are not attacked in this method of oxidation.



I



II

To obtain the tetrol a solution of anthracene (0·0025 mol.), osmium tetroxide (0·005 mol.) and pyridine (0·01 mol.) in pure benzene (20 ml.) was kept at room temperature for a fortnight with occasional shaking. The brown osmic ester complex which had separated was collected, washed with benzene, and dried in the air. It (1 gm.) was hydrolysed by heating on the water bath for three-quarters of an hour with a solution of crystalline sodium sulphite (5 gm.) in water (25 ml.) and ethanol (25 ml.). More ethanol was then added to precipitate the salts remaining in solution, and the whole was filtered. The black residue was extracted several times with hot alcohol, the extracts combined with the original filtrate, and the combined liquors concentrated under reduced pressure. The solid which separated after cooling was recrystallized from water, giving almost colourless leaflets (80 mgm.) of 1 : 2 : 3 : 4-*tetrahydroxy*-1 : 2 : 3 : 4 -*tetrahydroanthracene* (II), m.p. 241° (decomp.) (found: C, 68·2; H, 5·8. $C_{14}H_{14}O_4$ requires C, 68·3; H, 5·7 per cent). Its *tetraacetate*, obtained with boiling acetic anhydride-pyridine and purified by chromatography on silica, crystallized from benzene – light petroleum in colourless prisms, m.p. 215–217° (found: C, 64·0; H, 5·2. $C_{22}H_{22}O_8$ requires C, 63·8; H, 5·3 per cent).

We thank the British Empire Cancer Campaign for a grant.

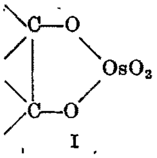
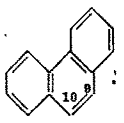
Relative Reactivity of Aromatic Double Bonds

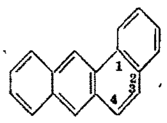
It is well known that osmium tetroxide readily reacts with ethylenic double bonds[1] with the formation of osmic esters (I), which may be converted into *cis*-diols. Criegee *et al.*[2] have found that phenanthrene (II) also reacts with osmium tetroxide. When the reaction was carried out in a non-aqueous solvent containing a little pyridine, a dark brown complex of 9 : 10-dihydrophenanthrene-9 : 10-diol-osmate and two molecules of pyridine was formed. Cook and Schoental[3] have recently extended this reaction to many other polycyclic aromatic hydrocarbons, and in every case addition to adjacent carbon atoms was found to take place, with the formation of a brown complex. With 1 : 2-benzanthracene (III), for example, reaction took place at the 3 : 4 positions. It seemed to us, therefore, that this reaction might be used to compare the relative reactivities of aromatic double bonds.



I



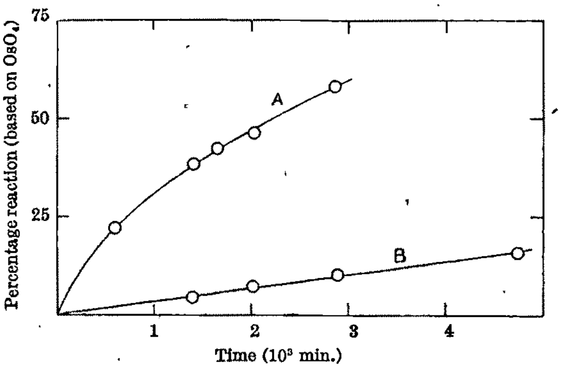
II



III

In a preliminary experiment with anthracene, phenanthrene and 1 : 2-benzanthracene, the hydrocarbon (0·0005 *M*) in pure benzene (15 c.c.) and pyridine (0·15 c.c.) was treated with osmium tetroxide (0·0005 *M*). As judged by the colours of the solutions at suitable intervals, anthracene and 1 : 2-benzanthracene appeared to be approximately equally reactive, and both seemed to react very much faster than phenanthrene. In view of this surprising result, we have carried out a more detailed comparison between phenanthrene and 1 : 2-benzanthracene. (Anthracene is not entirely satisfactory for comparison with phenanthrene, for Cook and Schoental[4] have found that this hydrocarbon reacts with two molecules of osmium tetroxide to form a complex which on hydrolysis yields a tetrol, and we are making a separate investigation of this reaction-rate.)

For the more accurate investigation we have carried out the reaction between the hydrocarbons and osmium tetroxide in chloroform solution, at 30° C.; aliquot portions being taken at suitable intervals and diluted with chloroform and pyridine. The colour intensities of these solutions were then estimated with a Spekker absorptiometer, using green filters. The instrument was calibrated with known concentrations of the appropriate complex; and it was also shown that absorption with an osmium tetroxide – chloroform – pyridine solution, which was yellow in colour, was negligible compared with that of the solution of the complex. The rates of reaction were measured under conditions leading to the production of a second-order rate-constant. The initial concentration of 1 : 2-benzanthracene was 0·04994 *M*, of phenanthrene 0·04996 *M*, and of osmium tetroxide 0·01354 *M*. With 1 : 2-benzanthracene, the reaction was followed until approximately 60 per cent of the osmium tetroxide had been consumed, and the mean rate-constant was found to be $1{\cdot}2 \times 10^{-4}$ (gm. mol. sec./litre)$^{-1}$. With phenanthrene, the rate constant was found to be $1{\cdot}2 \times 10^{-5}$ (gm. mol. sec./litre)$^{-1}$, the reaction being followed until 16 per cent of the osmium tetroxide had been used. 1 : 2-Benzanthracene, therefore, reacts approximately ten times as rapidly as phenanthrene (see graph).



CURVES SHOWING RATE OF REACTION OF OSMIUM TETROXIDE WITH 1 : 2-BENZANTHRACENE (CURVE *A*) AND PHENANTHRENE (CURVE *B*)

It is clear, therefore, that the reaction offers a useful method, not previously available, for the quantitative comparison of the relative reactivity of aromatic double bonds, and it may possibly prove useful in investigations on the Mills–Nixon effect and on bond fixation due to hydrogen bonding. The present investigation was undertaken in an attempt to estimate the validity of the quantum-mechanical calculations of Pullman[5], who has developed a theory attempting to correlate carcinogenic activity of polycyclic aromatic hydrocarbons with an optimum density of π-electrons at the *K* position (the 3 : 4 bond in benzanthracene). Her calculations for phenanthrene and benzanthracene do not appear to be in accord with our experimental results.

This work is being continued and extended.

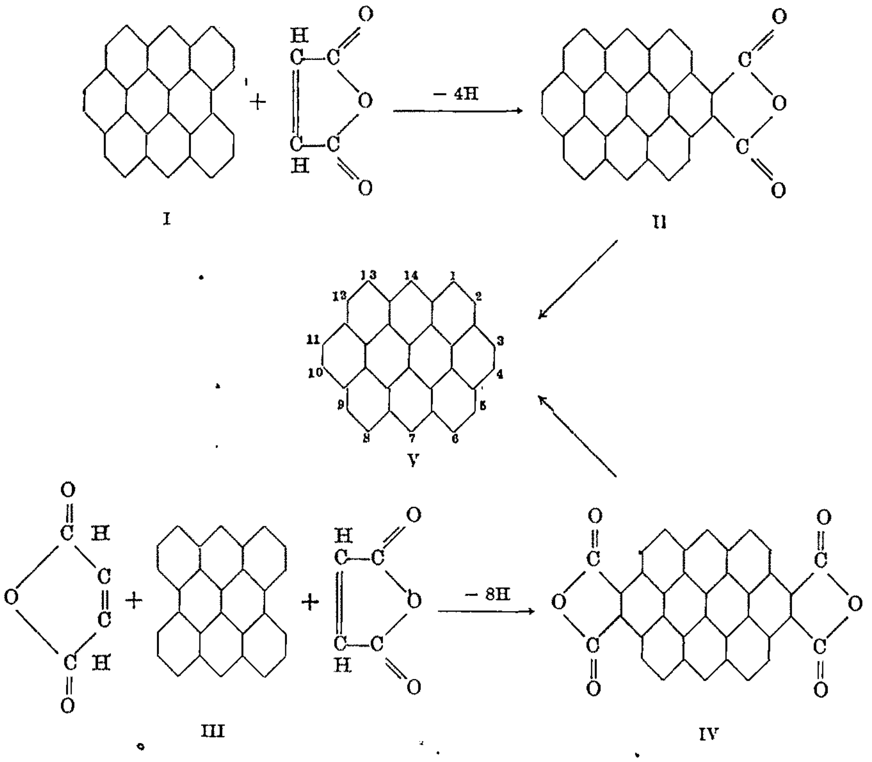
Synthesis of Ovalene

If perylene is boiled with maleic anhydride and nitrobenzene, 1 : 12-benzperylene-1′ : 2′-dicarboxylic acid anhydride is formed[1]. Under the same conditions *meso*-anthra-dianthrene[2] (I) yields quantitatively the anhydride (II), as dark red needles decomposing at 430° (uncorr.) (found: C, 86·48; H, 3·01. $C_{34}H_{12}O_3$ requires: C, 87·17; H, 2·58 per cent),



and *meso*-naphtha-dianthrene[2] (III) reacts twice to form the dianhydride (IV), as dark brown crystals, carbonizing at high temperature.

Both anhydrides II and IV give by decarboxylation with soda-lime at 400° in vacuum the same hydrocarbon (V), which consists of a naphthalene system surrounded by eight benzene rings. I have called it 'ovalene'. In the analogous hydrocarbon coronene one benzene ring is surrounded by six benzene rings. In the series *meso*-naphtha-dianthrene (III), *meso*-anthra-dianthrene (I), and ovalene (V), there is a change in colour from deep blue-green to violet and light orange-yellow, while perylene is golden, 1 : 12-benzperylene pale yellow and coronene paler yellow.

Ovalene sublimes in beautiful light orange needles. It can be recrystallized from 1-methylnaphthalene and melts at 473° (uncorr. evacuated, capillary). It dissolves in concentrated sulphuric acid to give a violet solution which becomes brown. The very dilute solution in benzene shows an orange fluorescence. $C_{32}H_{14}$ (398·43): cal. C, 96·46; H, 3·54; found C, 96·61; H, 3·72 per cent.

Colour Reagents for the Paper Chromatography of Sugars

THE application of paper chromatography to the separation[1], identification, and quantitative microdetermination[2] of the sugars, in investigations of the carbohydrate group, is an advance of no small importance. However, the use of ammoniacal silver nitrate, which gives a similarly coloured dark spot with all the reducing sugars, as colour reagent, often leads to uncertainty, especially when the *RF* values of the sugars are close.

In a current investigation of a polysaccharide, for example, which I carried out at the Chemical Laboratories of the University of Manchester, it was necessary to decide which one of the group, mannose, fructose, arabinose, was present in addition to several other sugars. The fact that the possibles were an aldose, ketose and pentose suggested the use of an acid solution of one of the phenols (phloroglucinol, orcinol, etc.) as a colour reagent. These phenols have long been used to test for the various groups of sugars, but are of limited use when dealing with complex mixtures in solution. This limitation is overcome by the spatial separation of the sugars during chromatography.

It has been found that colour reactions are readily obtained if the chromatogram, after preparation and drying in the usual manner, is sprayed with a solution of the phenol (10 ml. 1 per cent alcoholic solution

Phenols	Time of drying (min.)	Back-ground	Galactose Glucose Mannose	Fruct-ose	Xylose Arab-inose	Rham-nose
Resorcinol	3	—	—	Red	—	—
	10	Pink	—	Red	Blue	Yellow
Naphtha-resorcinol	10	Pink	Grey	Brown	Blue	Green

in 90 ml. 2N hydrochloric acid) and dried for 10 min at 85–95° C.

Phloroglucinol, orcinol, α-naphthol, resorcinol and naphtharesorcinol were tested. Resorcinol and naphtharesorcinol proved of wide application, and the colours obtained are shown in the accompanying table.

About 1 μl. of a 1 per cent solution of the sugar was spotted on filter paper and sprayed. The same colours were obtained in their proper spatial distribution when chromatograms of complex mixtures of the sugars were sprayed.

The qualitative identification of the sugars in a complex mixture is readily obtained in practice by spotting on six alternate spots of unknown and standard mixture. After running and drying, the paper is cut into three strips and sprayed with ammoniacal silver nitrate, resorcinol and naphtharesorcinol respectively. As standard mixture a solution of galactose, fructose, xylose and rhamnose (each sugar in 1 per cent concentration) is most suitable. By comparing the position and the colour of the spots on the strips an accurate picture of the composition of the mixture is obtained. Usually a satisfactory result can be obtained by merely spraying the whole chromatogram with naphtharesorcinol. Mannose and arabinose, which especially present difficulty in paper chromatography, are readily differentiated by a resorcinol spray.

It should be noted that non-reducing sugars such as sucrose also give a positive reaction.

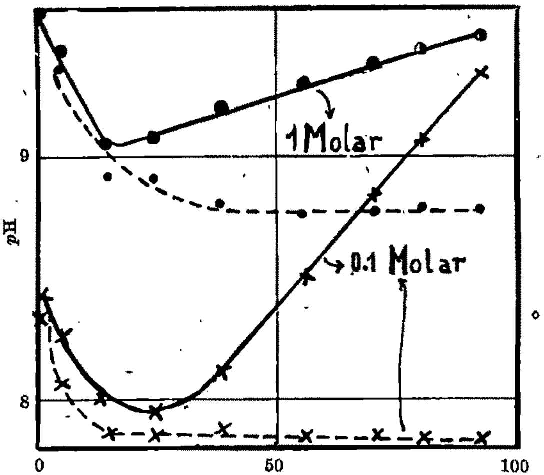
pH of Trisodium Citrate Solutions Stored under Customary Laboratory Conditions

During research on certain metallic complexes of citrate[1,2], we have observed that the pH of trisodium citrate solutions depends somewhat on their 'age'. Solutions, prepared at various times, showed differences of as much as 1·3 pH, though raw materials, methods of preparation and concentrations were identical. In view of the widespread chemical and clinical use of such solutions, it seemed of interest to investigate this phenomenon.

Two samples of a 0·1 molar and two of a 1 molar trisodium citrate solution were prepared by dissolving sodium citrate, gran., B.P. (supplied by Messrs. May and Baker, Ltd.) in distilled water. One sample of each concentration was stored in a 'Duraglas' brand flask (purchased from Messrs. Eimer and Amend, New York), and another in a flask coated with pure paraffin wax. The samples were kept under ordinary laboratory conditions for 92 days (June 2–September 1, 1947) and their pH was measured at intervals of 10–15 days. During this period the mean temperatures in Jerusalem were 22·0° in June, 23·9° in July and 25·0° in August. The measurements were discontinued on the 93rd day, because *Penicillium* moulds made their appearance. The pH measurements were carried out at 30° ± 0·1°, with a precision of ± 0·02 pH, using a Cambridge pH-meter (bench type).



Variation of pH with 'Duraglas' flasks (full lines) and paraffin-coated flasks (broken lines)

Results are plotted in the accompanying graph. During the first two to four weeks, there was a decrease in the pH of all four solutions. From this time onward, however, the solutions in paraffin-coated flasks showed practically *no further change*. Contrary to this, the two solutions stored in flasks with unprotected glass walls exhibited a continuous rise of pH, from the 24th to the 92nd day. This is consistent with the assumption that some of the glass is being dissolved. The rise of pH is about 1·3 for the 0·1 molar solution and only 0·5 for the 1 molar solution, both corresponding to the same approximate increase of the concentration of hydroxyl ions, namely, about 2 × 10^{-5} equivalents per litre.

In order to ascertain how carbon dioxide (which is present both in the distilled water used and in the atmosphere) affects the pH of the solutions, the following experiments were carried out. Solutions of trisodium citrate were prepared, using freshly boiled distilled water, and stored in flasks with paraffin coating. The pH of these solutions was found to be higher than of those prepared with unboiled water. Then, carbon dioxide was bubbled through them for thirty minutes. The pH, measured immediately afterwards, was much lower than any previously observed, but not constant enough for accurate determination. It increased slowly (at the rate of about 0·15 per 15 minutes), obviously because of escaping carbon dioxide. To obtain a constant value, pure nitrogen was bubbled through the solutions and the pH checked at intervals. After three hours, final pH values were reached, which remained unchanged when nitrogen was bubbled through for another two hours. Results of the experiments with carbon dioxide are summed up in the accompanying table.

It appears that the pH of pure uncontaminated trisodium citrate is about 9 in a 0·1-molar solution and 10·3 in molar solution. Solutions exposed to atmospheric carbon dioxide show a gradual decrease of pH (see graph) until constant values (7·8 for the 0·1-molar solution and 8·8 for the molar solution)

ACTION OF CARBON DIOXIDE

Molarity of trisodium citrate	pH						
	In CO_2-free solutions	After saturation with CO_2	After bubbling nitrogen through solutions				
			1 hr.	2 hr.	3 hr.	4 hr.	5 hr.
0·1	8·97	6·20–6·35*	6·91	7·43	7·82	7·86	7·84
1	10·30	6·90–7·03*	7·65	8·20	8·76	8·72	8·70

* *p*H not constant: rises at a rate of about 0·15 per 15 min.

are reached, after the lapse of three to four weeks. The same final *p*H may be obtained within a few hours (see table) by bubbling successively carbon dioxide and nitrogen through the solutions.

Citrate solutions ought, therefore, to be stored in paraffin-coated flasks if it is desired to keep their *p*H constant; furthermore, contamination by carbon dioxide must be avoided.

We have pleasure in thanking Miss T. Rayss for examining the *Penicillium* moulds.

Preparation of Rare-Earth Chlorides

THE preparation of chlorides of the rare-earth elements directly from monazite by chlorination in the presence of carbon possesses certain advantages over conventional methods. (1) Phosphorus is volatilized as oxychloride in a single operation and the chlorides may be obtained phosphate-free. Conventional methods involve lengthy operations for its complete removal, particularly from thorium. (2) Impurities present in the mineral (as well as those in the added carbon) are largely eliminated as volatile chlorides; for example, as the chlorides of iron, silicon, titanium, aluminium, zirconium and tin. (3) The anhydrous chlorides produced may be extracted either in water or non-aqueous solvents or recovered in a molten state.

The reaction has been studied by briquetting the powdered phosphate with wood charcoal, using rare-earth chlorides as a binding agent. The dried briquettes were heated to reaction temperature in a vertical tube, and a known weight of chlorine passed. Nitrogen was passed through the charge before and after reaction to remove moisture and oxygen and to displace residual volatiles. Condensation of phosphorus oxychloride served as a guide to the progress of reaction. The chlorinated briquettes were extracted with dilute nitric acid (*p*H 2), and the yield estimated by analysis of this solution.

Reaction proceeded smoothly when the phosphate and charcoal were finely ground and when the temperature was as close as possible to the sintering temperature of the briquettes (700–750° C.). The consumption of carbon indicated that the approximate course of the reaction was

$$RPO_4 + 3C + 3Cl_2 \rightarrow RCl_3 + POCl_3 + 3CO.$$

(*R* stands for rare-earth elements: a similar expression holds for thorium.) Some results are given in the accompanying table. The conditions were as follows. Temperature, 700° C.; dimensions of charge: height, 7 cm., cross-section, 2·6 cm.², weight, 50 gm.; weight-ratio monazite/carbon, 6·7; particle sizes, Tyler screens: phosphate, 100%–325, charcoal, 100%–200, briquettes, – 6 + 10; RCl_3, 1 gm. per 50 gm. of charge; monazite analysis: rare-earth oxides, 59·7 per cent; ThO_2, 6·8 per cent; P_2O_5, 27·4 per cent; insoluble in sulphuric acid, 2·0 per cent; ash in charcoal, 7·8 per cent.

Chlorine passed††		Yield*, %		Overall chlorine efficiency**

	95	89	9·2	31
0·70	20	34	Nil	56
	30	47	trace	52
	40	54	0·10	45
	145	90	9·1	21

* Corrected for RCl_3 used as binder.
** Calculated from data in columns 2, 3 and 4.
† No free chlorine evolved.
†† Theoretical consumption of chlorine, 33 gm.

No phosphate was detected in the extracts, which contained only small quantities of impurities, chiefly calcium and magnesium chlorides.

Under optimum conditions, it is therefore possible to obtain a 90 per cent yield of rare-earth chlorides of very satisfactory purity for an overall chlorine efficiency of 75 per cent. The real efficiency is undoubtedly greater than this, because several grams of chlorine are consumed by impurities. The time required to produce a 90 per cent yield is almost independent of the flow-rate; but the rate of reaction falls off very markedly after a 90 per cent yield has been attained.

Thorium is not chlorinated until approximately 50 per cent of the rare earths has been attacked, and thereafter reacts much more slowly than the latter. After extraction of soluble chlorides and separation of unconsumed carbon, a residue is obtained which corresponds in composition to a rare-earth phosphate in which the weight ratio $ThO_2/(ThO_2 + R_2O_3)$ has been increased from an initial value of 0·10 to 0·45.

At 800° C. the reaction becomes rapid, but the chlorides melt and a considerable amount of thorium chloride volatilizes. The reaction at high temperatures is under further investigation. A fuller account of results and experimental procedures will be published elsewhere.

Mechanism of Conductance by Hydrogen and Hydroxyl Ions in Aqueous Solutions

IT has been suggested[1–5] that the process of electrolytic conduction by hydrogen and hydroxyl ion in water involves, in addition to the mass transport of the hydrated ions, a proton transmission mechanism. This mechanism yields by means of a relatively small motion (*c.* 0·4 A.) of a proton as great a charge transport as would result from a much larger (*c.* 3 A.) motion of the entire ion.

I have attempted to determine whether this mechanism is, in fact, involved by measurement of the conductances of rapidly frozen aqueous solutions of electrolytes—solutions in which the contribution of the mass transport mechanism is presumably greatly depressed. Solutions of hydrochloric acid, nitric acid, hydrofluoric acid, potassium hydroxide, lithium hydroxide, potassium chloride, and lithium fluoride were cooled rapidly to liquid-air temperature, then heated to the temperature at which the conductance was to be determined. The conductances were determined in the temperature range − 120° C. to − 40° C. Each system was studied at temperatures lower than its lowest reported eutectic temperature; at these temperatures the frozen masses appeared solid and felt hard. At liquid-air temperature in all cases the specific conductances were less than the limit of detection (2×10^{-10} mho cm.$^{-1}$) of the apparatus. As the frozen solutions of the acids and bases were warmed to the temperature of measurement, the conductance rose quickly to a maximum, then decreased over a period of hours (presumably the decrease arises from a slow phase separation). The frozen solutions of salts showed no conductance at temperatures below their eutectics; this observation supports the assumption that the mass transport mechanism is insignificant. The maximum conductance was taken as characteristic of the acid and base solutions at each temperature. The measurements were made with a direct-current instrument at fields of 1–10 volts cm.$^{-1}$ and current densities at 10^{-8}–10^{-6} amp. cm.$^{-2}$.

The value of the conductance for a given solution and temperature could be reproduced only to within a factor of two or three, probably because of the cracking of the solid and variations in the amounts of solute 'frozen in'. Following are some typical results:

Substance	Temperature	Specific conductance
0·06 *N* HCl	− 115° C.	6×10^{-9} mho cm.$^{-1}$
0·06 *N* HCl	− 106	3×10^{-8}
0·06 *N* HCl	− 94	9×10^{-8}
0·08 *N* LiOH	− 69	2×10^{-9}
0·08 *N* LiOH	− 51	$1·5 \times 10^{-8}$
0·08 *N* LiOH	− 42	2×10^{-8}
0·056 *N* NHO_3	− 84	3×10^{-9}
0·056 *N* HNO_3	− 70	1×10^{-8}

The observation that the frozen solutions conduct strengthens the suggestion that the proton transmission mechanism contributes to the mobility of hydrogen and hydroxyl ions in aqueous solutions. It may be worthy of mention that estimates of activation energies for the conduction process, made either from ratios of conductances at various temperatures or by application of the absolute rate theory of Stearn and Eyring to the equivalent conductances at each temperature, yield values between 6 and 10 kcal. mole^{-1}. These values are, of course, very uncertain; nevertheless, they may suggest that rotation in the lattice is rate-determining, since the activation energy for rotation of a water molecule in ice has been estimated from the temperature dependence of relaxation time of polarization to be about 8 kcal. mole^{-1}.

In any event, it seems that the pure proton tunnelling mechanism of Bernal and Fowler cannot be the only one involved. Both the strong temperature-dependence of conductance in ice and the fact that deuterium ion in heavy water has an abnormally high conductance lead to this conclusion. Whether the tunnelling effect contributes significantly cannot be decided easily because of the control over the rate by rotation or some other comparatively slow process.

Volumetric Estimation of Thallium

A NUMBER of processes have been described for the volumetric estimation of thallium. All these methods are based on the oxidation of thallium from the thallous to the thallic state by potassium permanganate[1], bromate[2], iodate[3] or ceric sulphate[4] solutions; but no attempt has been made to use a precipitation reaction for this determination.

Bromophenolblue (tetrabromo - phenolsulphonaphthalein), which has been used previously as an acid–alkali indicator and as an adsorption indicator[5] in the determination of mercurous ions, has been found by me to be a very suitable indicator for the determination of thallous ions also. 10 c.c. of *N*/10 potassium iodide is mixed with four drops of 0·1 per cent solution of bromophenolblue in alcohol, and thallous nitrate solution (about *M*/10) is run in from the burette. When the exact equivalent amount of the solution has been added, half a drop in excess of the solution turns the yellow-coloured precipitate to a beautiful green colour, the end-point being reversible.

Further work is in progress. The details of the process will be published in detail elsewhere.

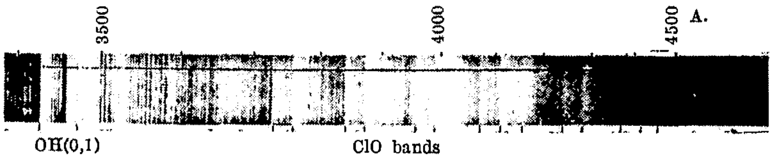
Band Spectrum of ClO in Flames

BAND systems attributed to the monoxides of bromine and iodine have been obtained by Vaidya[1,2] in flames of ethyl bromide and methyl iodide. Recently, Coleman and Gaydon[3] have made a further study of the BrO bands using various flames, including one of hydrogen burning in a mixture of oxygen and bromine vapour; the occurrence of the bands in this flame supports the assignment to BrO. There does not appear to be any detailed record of the corresponding band system of ClO, although Urey and Bates[4] reported the existence of a band system, which they thought to be due to ClO, when chlorine was introduced into an oxy-hydrogen flame. As part of a series of investigations on the inhibitory action of halogen compounds on flames, we have examined the spectrum of a flame of hydrogen burning in an atmosphere of oxygen mixed with a little chlorine. A system of bands has been obtained in the blue to near ultra-violet, which appear to be analogous to the known systems of BrO and IO and



SPECTRUM OF THE FLAME OF HYDROGEN BURNING IN A MIXTURE OF OXYGEN AND CHLORINE

which may therefore be assigned to ClO. The bands do not occur readily when chlorine is introduced into a carbon monoxide – oxygen flame, but have been observed, very weakly, in the outer cone of a methyl chloride – oxygen flame.

The bands, which are superposed on a fairly strong continuous background, are degraded to the red and appear to possess a fairly simple vibrational structure. Unfortunately, the heads are not well defined, and overlapping by strong bands of OH renders accurate measurement and reliable analysis difficult. Photographs have been taken with a medium quartz spectrograph (as in illustration), using plates of high contrast, and also with a large Littrow-type quartz spectrograph giving a dispersion of about 5 A./mm. in the region of the bands. Under the large dispersion the rotational structure is seen to be complex ; heads are difficult to locate, and the chlorine isotope effect could not be found owing to the complexity. With the smaller dispersion, the band heads listed in the accompanying table were measured ; the measures are accurate to about 2 A. in most cases, but in a few difficult cases there is a possibility of errors so large as 5 A. The bands have been arranged into a provisional vibrational scheme using intervals of about 780 cm.$^{-1}$, decreasing to less than 700 for ω'' and about 550 cm.$^{-1}$ for ω'. The bands fall on an open Franck–Condon parabola, and it is not possible to assign definite values for v'' ; it would not be surprising if x in the table was about 3, making ω'' a little more than 800 cm.$^{-1}$.

nteraction Terms in Molecular Vibrations

IN a recent communication[1], Coulson, Duchesne and Manneback have pointed out that the positive sign of the cross-term constant, g_c, in the P.E. function of the water molecule

$$2V = f_1(\overline{\Delta r_1}^2 + \overline{\Delta r_2}^2) + 2f_{12}\,.\,\Delta r_1\,.\,\Delta r_2 + r_1 r_2 f_\theta . \overline{\Delta\theta}^2 + 2r_1 g_c(\Delta r_1 + \Delta r_2).\Delta\theta$$

can be accounted for by supposing that the hybridization of the oxygen bond-forming orbitals changes during a vibration. We had come to exactly the same conclusion, and our reasons for this are contained in a communication to the Faraday Society which is awaiting publication[2].

We were led to our conclusion more particularly by the sign of f_{12}, which is negative. This implies that, as one OH-bond contracts, the other tends to contract also. We had first supposed that the departure from the simple valency force-field might be due to repulsion between the hydrogen atoms. But, if this were so, movement of one hydrogen atom towards the oxygen atom would force the other away. We were therefore led to conclude that as one OH-bond contracts it assumes more s-character, which results in the other bond assuming more s-character and its equilibrium-length decreasing. This explanation was confirmed by the fact that it accounted for the positive sign of g_c also. So we concluded that the size of the HOH angle was due to the fact that the oxygen bond-forming orbitals in water had considerable s-character, rather than because of repulsion between the hydrogen atoms.

If the repulsion between the hydrogen atoms is given by

$$V = V_0 + A(\Delta R) + \tfrac{1}{2}B(\Delta R)^2$$

for small displacements, ΔR, from the HH distance in the equilibrium configuration, the contribution of A and B to the cross-terms f_{12} and g_c can be shown to be

$$\begin{array}{ll} 0{\cdot}313\,B - 0{\cdot}124\,A & \text{to } f_{12} \\ 0{\cdot}242\,B + 0{\cdot}160\,A & \text{to } g_c. \end{array}$$

The signs of the contributions to g_c and f_{12} will depend, therefore, on the signs and relative magnitudes of A and B. We cannot, therefore, agree with Coulson, Duchesne and Manneback that it is necessary "that the contributions to the interaction constants f_{12} and g_c that arise from the force between the two non-bonded atoms have the same sign". This will only be true when the first terms involving B, d^2V/dR^2, outweigh the second terms involving A, dV/dR. However, in the present case, it does not seem that the force between the non-bonded atoms is an important factor. Urey and Bradley[3] pointed out that this factor was important in accounting for the departures from the simple valency force-field in molecules such as carbon tetrachloride. We have developed their ideas somewhat further for the tetrahalides of some Group IV elements in two other papers that are awaiting publication[4], and have shown that the repulsion that exists is of the magnitude that would be expected if it arises from Van der Waals' type interaction.

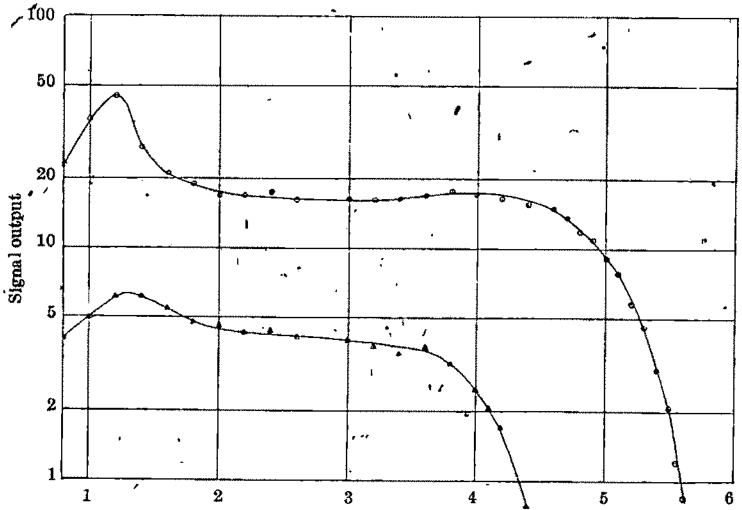
Spectral Response of Lead Selenide

MICRO-CRYSTALLINE layers of lead selenide are known to show photo-conductivity when illuminated by infra-red radiation, in a manner similar to that shown by lead sulphide. Measurements made in Germany during the War indicate that for lead selenide the long wave-length limit of sensitivity lies farther towards the far infra-red[1]. More recent experiments by Blackwell, Simpson and Sutherland[2] on the spectral response of lead selenide confirm this. Up to the present, however, the accurate determination of the long-wave limit has been impossible because of the very strong absorption in this region of the spectrum of 'Pyrex' and other glasses from which the photo-conductive cells have been made. We have recently developed a technique whereby a sensitive layer may be made in a cell with a window of *KRS*5 material (a mixture of thallium bromide and iodide which has a uniform transmission of about 65 per cent from 1 to 35 μ).

The cell is made in an envelope of the usual Dewar flask type except that the outer wall is formed into an elongated neck opposite the layer electrodes, which are on the inner wall. Initially a layer of lead selenide is evaporated on to the electrodes *in vacuo*, and then the end of the glass neck is cut off, ground flat, and the window sealed on with vacuum wax. The layer is then treated by heating to a temperature just below its subliming point (about 405° C.) *in vacuo* for several hours. For this treatment the inside of the Dewar vessel is filled with a molten (low melting point) alloy maintained at the appropriate temperature by means of a small immersion heater. Finally, the layer must be recrystallized by evaporating on to the outer wall of the flask and then back on to the electrodes, when a sensitive, high-resistance layer is obtained. Throughout these processes the window is kept cool by standing in cold water.

The accompanying diagram shows the spectral response of lead selenide for constant incident energy at 195° K. and 90° K. The shift to longer wave-lengths on cooling is analogous to that observed for lead sulphide[3]. Taking the flat portion of the curve as the datum-level, the response at liquid oxygen temperature is down to 50 per cent at 5·0 μ, indicating about 1·0 μ shift from the 195° K. curve.



SPECTRAL SENSITIVITY OF LEAD SELENIDE LAYER, SHOWING SIGNAL OUTPUT FROM THE LAYER FOR CONSTANT INCIDENT ENERGY. ⊙, 90° K.; △, 195° K. (on same scale)

The peak found at 1·2 μ is believed to be due to impurities and not inherently characteristic of the main lattice. At longer wave-lengths the response curve differs somewhat from that of other workers[1,2], who find a slight secondary peak. The presence of this peak may perhaps be connected with the varying transmission of the layer with wave-length. If the layer is too thin, all the incident energy is no longer absorbed at the longer wave-lengths, giving a false impression of the shape of the spectral sensitivity curve.

The layer which is the subject of this note was therefore made relatively thick (estimated as somewhat greater than 1 μ from the mass and area of the layer). Previous measurements in this laboratory have shown that layers appreciably thinner than this have considerable transmission in the region of 5 μ.

The spectrometer used was a double-dispersion instrument using lithium fluoride prisms and having a high degree of freedom from scatter.

Our thanks are due to Dr. G. B. B. M. Sutherland and Mr. O. Simpson, of the University of Cambridge, for communicating to us, before publication, their method of making sensitive lead selenide cells[4] and their recent spectral response measurements[2]; also to the Ministry of Supply for permission to publish this letter.

Pinhole Radiography of Magnetrons

'PINHOLE RADIOGRAPHY' is extensively used[1] to study the size and shape of the focal spot of an X-ray tube. Where electrons strike the anode, X-rays are emitted in all directions; a camera, with a pinhole in a sheet opaque to X-rays in place of the lens, can be used to record an X-ray image of the bombarded area.

Hitherto, magnetrons[2] have operated at anode voltages too low for X-rays to escape from the tube envelope in appreciable intensity. We have recently been working on a high-power (2,000 kW.) pulsed 10 cm. magnetron, operating at 47 kV. anode voltage, 90-amp peak, 135-m.amp. mean anode current[3]. Having observed X-ray emission from this valve (10^{-5} r./sec. at 1 metre distance) we decided to make the following experiment.

The normal electromagnet gap of 8 cm. was increased to 11·5 cm., while maintaining the magnetic field at 1,600 oersteds. The valve was set up with one end-plate against a pole-face. A sheet of lead, 2 mm. thick, was placed against the other end-plate, and contained a pinhole situated on the axis of the valve.

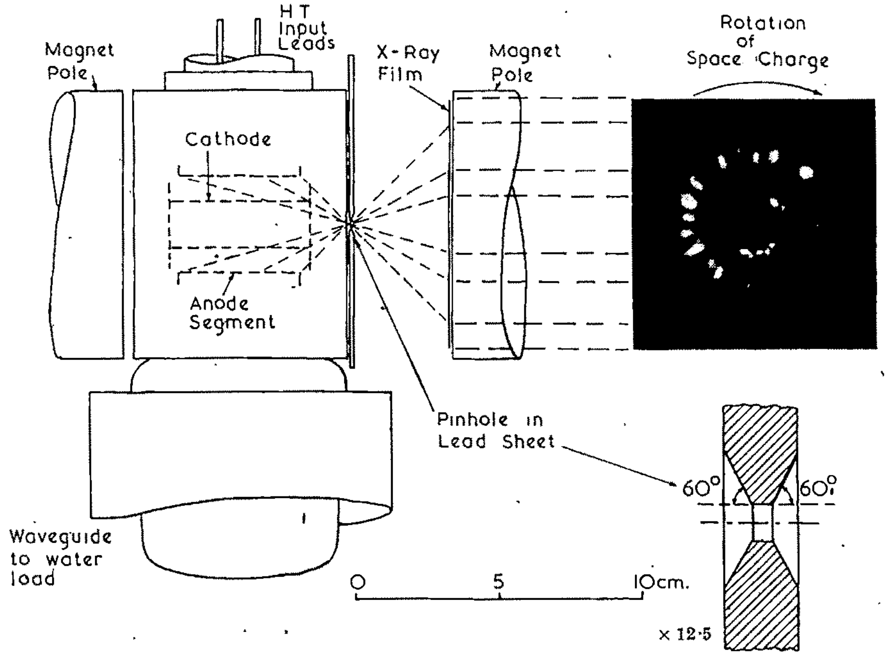
An X-ray film (Kodak 'Industrex' Type *D*) in a black paper envelope was pressed against the second pole-face. The general arrangement is shown in the figure, which includes a detail enlargement of the pinhole.

The accompanying radiograph is reproduced from a print of a negative obtained with a 10-min. exposure. The print shows bombardment of the following areas: (1) the 'far' end of the segments (small central ring of bright spots); (2) the 'near' end of some of the segments; (3) two or three of the spirally disposed 'echelon' strap wires at the near end; (4) limited areas on each segment between the near end and the middle.

The effects (1), (2) and (3) are thought to be incidental to the proper working of the magnetron. (Possibly they arise from the frequent flash-arcs taking place during the run.) On this view, (4) represents bombardment by the 'useful' electrons. It is of interest to note:

(*a*) Marked inequality of intensity on different segments.

(*b*) Concentration of bombardment on each segment in a line at the 'leading' edge and a patch near the 'trailing' edge.



(*c*) The apparent absence of bombardment near the middle plane of the valve, which may be due to increased absorption by the slant thickness (about 1 mm.) of the nickel cathode tube. (All rays recorded are filtered through the nickel end-disk of the cathode, 0·5 mm. thick, and 1·5 mm. of copper in the end-plate of the valve.) However, another exposure, with the pinhole eccentric to avoid absorption by the cathode tube of X-rays leaving the whole of two or three segments, showed no axial extension of the bombardment areas. The concentration towards the near end is perhaps due to the slightly weaker magnetic field near this end.

These first results already show that pinhole radiography can give valuable information about electron motion in magnetrons. We became aware of the value of pinhole radiography, in connexion with other high-voltage electronic valves, by learning of the prior experiments of Mr. A. G. Long[4], of Messrs. Newton and Wright, Ltd., on high-voltage rectifiers.

Latent Infection in *Coffea arabica* L.

PROF. S. R. BOSE's article[1] dealing with the occurrence of *Phomopsis casuarinæ* F. Tassi throughout the tissues of *Casuarina equisetifolia* Forst. prompts me to record some observations made in 1940 and 1941 on the presence of various fungi in the tissues of Arabic coffee (*Coffea arabica* L.).

While investigating a disease of green coffee berries which is caused by a variety of *Colletotrichum coffeanum* Noack[2], healthy leaf, green berry, stem and pedicel tissues were tested for the presence of latent infections using a mercuric chloride–saponin solution as the surface sterilizing fluid. Practically every piece of tissue tested, down to one millimetre square pieces of leaf tissue, were found to produce fungal growth when cultured on prune agar. *Colletotrichum coffeanum*, in a large variety of forms, was most frequently obtained, but a species of *Phoma* and a species of *Phomopsis* were also frequently isolated. The fact that these fungi are present as latent infections on almost all healthy coffee tissue explains the constancy with which they fructify on tissues which have died from carbohydrate or nitrogen deficiencies, sun-scorch, etc., and explains why a number of physiological diseases have, in the past, been considered to be due to fungal attack.

The strains of *Colletotrichum coffeanum* isolated showed similar variations to those noted by Burger[3] for *C. glœosporioides* Penz. It was observed, however, that certain forms were most frequently isolated from certain parts of the plant. Those with short spores, sparse whitish mycelium and with the chlamydospores simple or absent were mainly found on twigs, whereas those with longer spores, abundant greenish mycelium and abundant convoluted chlamydospores occurred most frequently on green fruits; intermediate forms were found mainly on leaves and pedicels. The form causing the disease of ripe berries, which is known as 'brown blight', is of this type, the extreme development of which is represented by the form which causes the serious disease of green berries known as 'coffee berry disease'. This form is characterized by the spores being produced separately on branches over the entire mycelium instead of being massed on stromata as with all the other forms. The forms on leaves and stems never appear to cause disease symptoms, though certain minute yellow spots on mature leaves may be due to the presence of the fungi. Fructification only occurs when the bark dies (perhaps somewhat prematurely) or the leaves are shed. It is interesting to note that the forms which make up the morphological series appear thus not only to be associated with different parts of the plant, but also with differing degrees of parasitism.

A similar series of forms appears to exist in the *Phoma* sp., again distinguished by increasing length of spores and by increasing coloration of mycelium. The individual forms also show a similar trend of preference for different parts of the plant. None, however, has been observed to produce a noticeably diseased condition. The *Phomopsis* sp., on the other hand, showed no obvious polymorphy.

There is some evidence to suggest that premature shedding of leaf, irregular bark ripening and uneven ripening of the berry may be associated with the development of the less pathogenic latent infection fungi in senescent tissues.

Persistence of D.D.T. and Benzene Hexachloride in Soil

THE use of 2 : 2-*bis*-(*p*-chlorophenyl)-1 : 1 : 1-trichlorethane (*D.D.T.*) and benzene hexachloride as soil insecticides raises the question of the length of time for which these substances will persist in soil. There is already much indirect evidence that both these substances are satisfactory in this respect; but the possibility exists that they may suffer bacterial[1] or other decomposition in soil, as do many organic compounds. So far as I am aware, this problem of persistence has not so far been the subject of direct chemical investigation.

In experiments commenced here some eighteen months ago, both *D.D.T.* and benzene hexachloride (mixed isomers containing 10 per cent gamma isomer) were incorporated at a high concentration (2 per cent) with acid and with alkaline soils. Treated and control soils were kept in the open, and the residual insecticide determined chemically at intervals. In view of the possibility that a decomposition in soil might involve dehydrochlorination, determinations were also made of soil chloride, chloride leached and *p*H.

Similar determinations were carried out in a second series of experiments in which soils kept under laboratory conditions were subjected to controlled leaching at intervals.

The results reveal the marked persistence of these insecticides under the conditions employed. Thus, even after eighteen months, more than 95 per cent of the *D.D.T.* and 80–94 per cent of the benzene hexachloride can be recovered. The chloride estimations on soils and leachings have not indicated the release of more than traces of inorganic chloride. No regular changes in *p*H have been observed.

Counts of soil bacteria, estimated by the plate method, suggest that neither *D.D.T.* nor benzene hexachloride has an adverse effect on the bacterial population.

While it is recognized that the concentration of insecticide used in these experiments is very considerably greater than would ever be used in practice, it is interesting to note that whereas the *D.D.T.*-treated soils permit normal germination and early growth of cress, oats and wheat, those treated with benzene hexachloride inhibit root development. Further, the benzene hexachloride soils do not permit root development in the case of sugar beet, cabbage and flax. Here the *D.D.T.* treatment results in a somewhat lower percentage germination, although early growth is then normal. Oats and wheat are particularly susceptible to benzene hexachloride, and suppression of the radicle occurs even when the concentration of this substance is reduced to 0·02 per cent by admixture with the control soil.

Details of this work will be published elsewhere.

Newly Discovered Submarine Canyons of New Guinea and South Australia

FAIR charts of the Morobe area, New Guinea, which were recently made available to me by the Royal Australian Navy, show three huge depressions across the continental shelf. These are submarine canyons, apparently the first to be discovered off New Guinea. They extend to within less than a mile of the modern coast and their heads oppose outlets of the Rivers Gira, Eia and Waria, after which they have been named. The bottom gradients of the submarine canyons average up to 10 per cent across the continental shelf, which is about ten miles wide. They range to seven and eight hundred fathoms in depth at the shelf edge, and no details are known of the structures more than a mile or two beyond that limit.

The local sea floor is reported to be of soft volcanic muds, while coral growths line the shelf edge, rising from depths of from forty to seventy fathoms as barrier reefs. Minor coral growths occur at intervals along the submarine canyon rims. On the assumption that reef corals do not flourish in water deeper than about 20–30 fathoms, it is inferred that sea-level fell relatively by at least 40–50 fathoms at the time of barrier reef establishment. Unfortunately, nothing is known accurately of local land movements during the interval of canyon formation.

In keeping with Daly's theory[1] of submarine canyon development, which holds that muddy bottom density currents eroded the canyons during low sea-level periods of the Pleistocene, it is considered that canyon development proceeded contemporaneously with barrier reef establishment. However, in the present case, evidence suggests that submarine canyon erosion was initiated by silt-laden river waters entering the sea locally during the low sea-level phases, rather than simply by shore wave action on exposed continental shelf sediments. If the latter process was widely developed, it is thought that barrier reef establishment would have been inhibited or prevented. A possible counter to this argument, namely, that the muddy fraction of the shelf edge sediments would have been winnowed out during the early part of a low sea-level stand, is weakened by the fact that it would reduce the time interval of effective erosion by such inferred shore suspension currents too greatly.

Of the Murray submarine canyons, off the South Australian coast, little is yet known. They were located by the naval survey vessel H.M.A.S. *Lachlan*, by tracing the 100-fathom line for about eighty miles in the vicinity of the Murray River mouth. The deep submarine canyon structures occur in a width of less than four miles, although the remainder of the survey course revealed no other significant break.

The submarine canyons are thought to be genetically related to drowned courses of the Murray River, which is the only large river at present entering the sea locally. Along the line of the echo-sounding traverse, the three structures, named respectively the West, Central and East Murray submarine canyons, bottomed at approximately 550, 625 and 750 fathoms. The central and east members are separated by a low but definite ridge.

It is not known whether the three submarine canyons are essentially parallel structures or part of an elongated dendritic pattern. Investigations to be carried out in the future should solve this problem.

Concerning canyon triplicity, in a paper on the two groups of submarine canyons now in the press[2], I have advanced two theories as alternative possible explanations. Both relate to the repeated sea-level falls of the Pleistocene glacial phases, during which erosion by means of bottom density currents is considered (Daly's theory) to have been at a maximum.

Units and Useful Range in Photo-electric Colorimetry

WE value the remarks of Drs. Edisbury, Taylor and Gridgeman[1] on a new unit in photo-electric colorimetry[2]. Opinions do not seem at variance that measurements should be made at approximately the same optical density[1,2], that—provided the Beer – Lambert law be valid—the relation of the proposed unit $W^{50}_{1\,\text{cm.}}$ to the usual $E^{1\%}_{1\,\text{cm.}}$ can be expressed by:

$$E^{1\%}_{1\,\text{cm.}} = \frac{0\cdot00301}{W^{50}_{1\,\text{cm.}}},$$

and that E (1%, 1 cm.) is certainly less cumbersome to print than $E^{1\%}_{1\,\text{cm.}}$. Title and text of our letter[2], however, should have made it clear that we had photo-electric colorimeters (absorptiometers) in mind. Though it was shown by Twyman and Lothian[3] that 0·4343 is the best density for this type of instrument, it was also stated that ". . . we may use densities between 0·2 and 0·8 without any considerable loss of accuracy". This range covers easily the proposed half-value and adjacent auxiliary readings used for interpolating $W^{50}_{1\,\text{cm.}}$. An even wider range (0·2–1·2) is recommended elsewhere[4] for an instrument other than ours. The statement[1] that E (1%, 1 cm.) is merely a standard expression that does not carry the implication that one must measure the optical density of a 1 per cent solution in a 1 cm. cell may probably be correct, but not necessarily so, and does not seem to be endorsed unanimously; for Guild[5] inferred regarding accuracy in spectrophotometry that ". . . our terminology should be kept in as close correspondence as possible with the physical magnitudes actually handled in our experiments", strongly deprecating the use of derived magnitudes. Though the proposed half-value is inversely related to quantity, this need not impair its applicability; for a similar magnitude, the half-value layer is a standard expression in X-ray technique[6].

Thus the major practical point in dispute seems to be, how far the useful range extends towards both ends of the scale. As many extraneous factors influence the final accuracy, the limits of the useful range have to be established by experiment. To test this, sample and blank are compared, say, twenty times, whence a mean and its standard deviation are obtained. From the mean plus/minus sigma, and from the Beer – Lambert law, the error prevailing at this point of the scale can be estimated. A few pilot measurements towards either end of the scale will readily establish fiducial limits. 920 measurements performed on different concentrations of copper sulphate in water did not reveal any significant difference in accuracy between 10–90 per cent transmission. Within this range, two thirds of all observations fell within the limits ± 0·88 per cent weight of copper sulphate. The corresponding error below and above this range was 2·60 per cent and 2·56 per cent respectively.

[6] Pohle, E. A., and Chamberlain, W. E., "Theoretical Principles of Roentgen Therapy" (Lea and Febiger, Philadelphia, 1938).

THE major practical point in dispute is not "how far the useful range extends towards both ends of the scale" (though we believe this to be narrower than many published figures imply), but whether the proposed new unit fulfils any useful function not already covered by the old; and on this issue we have nothing to add to our original arguments. We would ask only that anyone who still prefers to use the 'half-value' should also, for the convenience of the reader, give the equivalent E (1%, 1 cm.) value.

HIGH-ALTITUDE MEASUREMENTS ON COSMIC RAYS

Penetrating Cosmic Ray Showers

THE penetrating shower set P, described in a previous communication[1], has now been transported to the Scientific Station, Jungfraujoch, altitude 3457 metres (atmospheric pressure = 50 cm.), and the transition curves of penetrating showers, produced in paraffin, aluminium and lead placed over the set P, studied there. In addition to the apparatus illustrated in our earlier note, four unscreened trays of counters, $E_1 \ldots E_4$, of areas 230, 460, 920 and 1,840 cm.^{2} respectively, were placed near the penetrating shower set, P, for recording the presence of air showers. Also the side and end screens of the set, P, were increased from 10 cm. to 15 cm. of lead. The seven-fold coincidences of P were recorded and, in addition, coincidences in P accompanied by a discharge of each of the four air-shower trays were recorded separately.

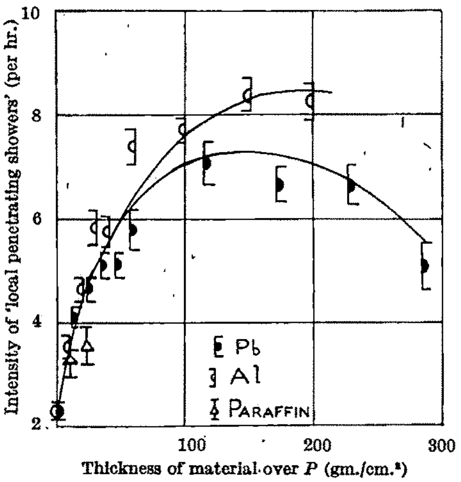

Fig. 1

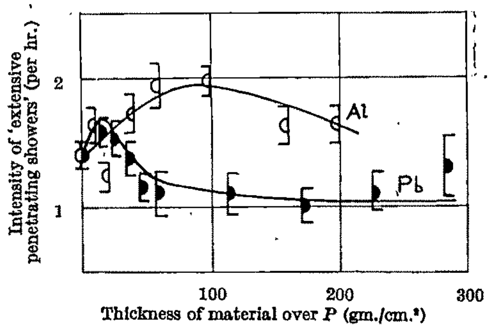

Fig. 2

Following the nomenclature of Jánossy and Broadbent[2], we call seven-fold coincidences in P, unaccompanied by discharges in the trays E, 'local penetrating showers', while seven-fold coincidences in P, accompanied by discharges of the trays E, are defined as 'extensive penetrating showers'. The importance of distinguishing between these two types of penetrating shower is illustrated by the work of Jánossy and Broadbent[2], who have shown that the intensity and transition curves for local penetrating showers are consistent with the view that they are caused by nucleons of the primary cosmic ray flux arriving on the top of the atmosphere. The interpretation of extensive penetrating showers is not so unambiguous at the moment. We discuss our results for these two types of shower separately.

(a) *Local Penetrating Showers.* The transition curves obtained for these showers are shown in Fig. 1, where the abscissæ give the thickness of different materials expressed in gm./cm.^{2}. It will be noted that initially the results all lie on the same curve, the results for lead and aluminium differing slightly for the largest thicknesses studied. This divergence is possibly due to the geometrical difference in the arrangement of the absorbers placed over P caused by the difference in density of the two substances. An attempt was made to counteract this density effect by spacing out the lead, but it is not possible to compensate exactly.

A comparison with the sea-level results of Jánossy and Broadbent shows that the intensity at Jungfraujoch is 28 times the sea-level intensity, which corresponds to a 'range' of the primaries causing them of 120 gm./cm.^{2}, and this again is consistent with the primary nucleon hypothesis.

(b) *Extensive Penetrating Showers.* The transition curves for extensive penetrating showers, measured using the tray E_4, is shown in Fig. 2, plotted on the same mass-scale as Fig. 1. It will be noted that these transition curves are typical cascade curves.

The intensity of this type of shower is only 10 times the sea-level intensity, and this is consistent with the increase of 12 in the intensity of air showers recorded by Auger at this same station.

Penetrating Bursts

MEASUREMENTS at sea-level on the existence of penetrating particles in ionization bursts have already been briefly reported[1]. We have now constructed an apparatus more sensitive to this type of burst, and after a short run at sea-level have carried out measurements on penetrating bursts at the Scientific Station at the Jungfraujoch.

The apparatus is illustrated in Fig. 1. An aluminium ionization chamber B, of 1·5 litres capacity and of wall thickness 1·25 cm., was filled with pure argon to a pressure of 30 atmospheres. Above and below the chamber were placed cylindrical screens of lead A and D, of thickness 15 cm. or greater, as shown. Furthermore, the ends were closed by lead screens of thickness 12 cm. In the lower screen D is a concentric slot E, in which were placed eighteen Geiger–Müller counters. Similarly, under the ionization chamber 9 Geiger–Müller counters C were placed, divided into three groups of 3, as shown. Further, the screens were flanked on each side by trays of counters I, II, III, IV, for the detection of air showers. These air-shower trays consisted of 1, 2, 4 and 8 counters respectively, each counter being of area 230 cm.^{2}.

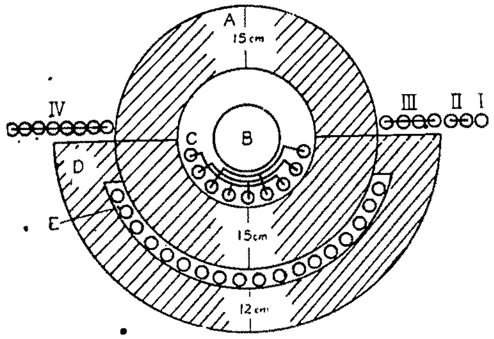

Fig. 1. GENERAL ARRANGEMENT OF APPARATUS

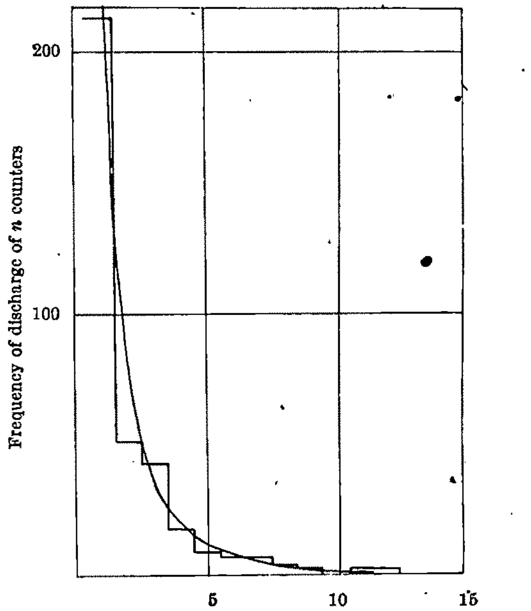
The voltage impulses produced by bursts of ionization in the chamber were amplified and recorded by a continuous camera, in a normal manner. To each of the lower counters 1 . . . 18 in *E*, and the air-shower trays I . . . IV, lamps were connected via separate amplifiers, and a given lamp was energized if a burst occurred accompanied by a three-fold coincidence in the upper counters *C*, plus a discharge in the corresponding counter to which it was connected.

From separate control experiments, it was shown that the majority of bursts accompanied by a discharge of only one of the lower counters was due to accidental coincidences, whereas those bursts accompanied by a discharge of more than one lower counter could not be so. Bursts accompanied by a discharge of more than one lower counter will be defined as 'penetrating bursts'. In the same way that Jánossy and Broadbent[2] showed the importance of distinguishing between so-called 'local' and 'extensive' penetrating showers, so we find it convenient to separate penetrating bursts into those associated with air showers, which we shall call 'extensive penetrating bursts', and those penetrating bursts unaccompanied by a discharge in the air-shower trays I–IV, which we shall call 'local penetrating bursts'. The fact that these two types of penetrating bursts are essentially different is shown in Figs. 2*a* and 2*b*, in which the frequency of discharge of *n* of the lower counters is plotted against *n* for local and for extensive penetrating bursts, observed in a period of 120 hours. While the size distribution for local bursts varies approximately as $1/n^2$, the size-distribution for extensive bursts seems to be given approximately by the Poisson distribution for $\bar{n} = 5$ or 6.

The intensities of the various types of burst are given in the table :

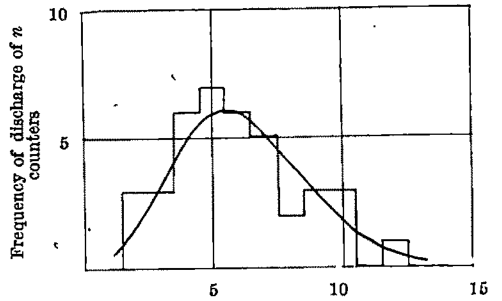
Type of burst	$R(>N)$ = Rate/hour of bursts of size $> N$							
	N							
	20	30	40	60	80	100	150	200
All bursts	12·6±0·34	3·52±0·18	1·81±0·13	0·89±0·06	0·41±0·06	0·25±0·05	0·11±0·03	0·095±0·03
Penetrating bursts	1·56±0·12	0·71±0·08	0·48±0·07	0·33±0·06	0·16±0·04	0·12±0·03	0·10±0·03	0·076±0·03
Extensive penetrating bursts	0·31±0·05	0·20±0·04	0·11±0·03	0·10±0·03	0·095±0·03	0·085±0·03	0·085±0·03	0·066±0·025

These results are plotted on logarithmic scales in Fig. 3. The slope of curve (1) for all bursts is $-2·2$, giving $R(>N)$ = const. $N^{-2·2}$, whereas the size contribution for penetrating bursts is quite different. It will be noted that of the largest bursts measured ($N>200$), the majority are penetrating and also extensive. The increase of burst intensity over the sea-level figure is a factor of 3·9, and this is about the amount by which penetrating bursts have increased with altitude.



No. of counters discharged simultaneously (*n*). Smooth curve, $1/n^2$

Fig. 2*a*. LOCAL BURSTS



No. of counters discharged simultaneously (*n*). Smooth curve, Poisson distribution, $\bar{n} = 6$

Fig. 2*b*. EXTENSIVE PENETRATING BURSTS

Penetrating bursts thus show much less of an increase with altitude than do penetrating showers[3], and we can therefore eliminate the nucleon component as the primary agent of penetrating bursts.

The interpretation of local penetrating bursts is perhaps the simplest. We have divided up these bursts into groups of different size, and measured the total number of lower counters discharged by bursts in the various groups. In Fig. 4 we have plotted the number of counters discharged per local penetrating burst as a function of the mean burst size of the group.

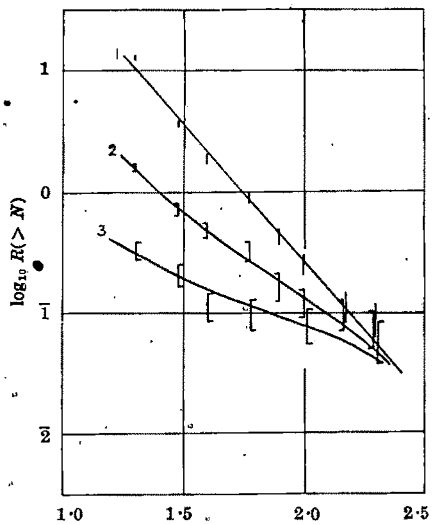


Fig. 3. INTENSITY OF BURSTS: N IS SIZE OF BURST; $R(>N)$ IS RATE/HOUR OF BURSTS OF SIZE GREATER THAN N. 1, ALL BURSTS. 2, PENETRATING BURSTS. 3, 'EXTENSIVE' PENETRATING BURSTS

The relation appears to be linear, and on the average one counter is discharged per local burst of 130 rays. The efficiency of collection of the lower tray is about $\frac{1}{4}$, and it therefore appears possible that local bursts contain on the average 3/130, or about $2\frac{1}{2}$ per cent of mesons, and are apparently caused by mesons.

The extensive penetrating bursts would appear on the average to be associated with the passage of something like eighteen penetrating particles through the lower half of the apparatus.

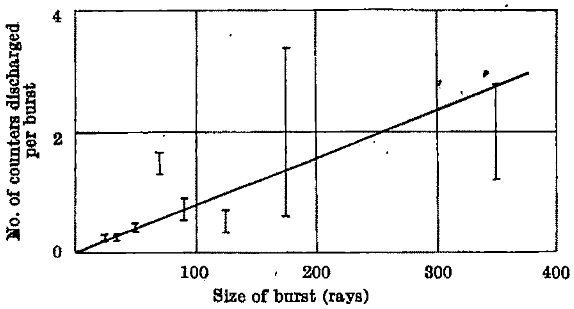

Fig. 4. VARIATION OF NUMBER OF COUNTERS DISCHARGED BY 'LOCAL PENETRATING BURSTS'

It would appear that additional processes are involved in burst production, under thick lead, over and above the creation of high-energy electrons and photons by mesons, and the subsequent cascade development of the former. For bursts of size greater than 100, these additional processes are involved in a large fraction of bursts, and this would appear to invalidate the arguments put forward for assigning the value 0 to the spin of the cosmic ray meson[4], based on measurements of burst production under thick materials.

STRUCTURE OF TURNIP YELLOW MOSAIC VIRUS CRYSTALS IN THE ELECTRON MICROSCOPE

By DR. V. E. COSSLETT
(I.C.I. Fellow)
Cavendish Laboratory, Cambridge
AND
DR. ROY MARKHAM
Plant Virus Unit, Molteno Institute, Cambridge

IT is known from examination in the electron microscope that turnip yellow mosaic virus[1] consists, in the dry state, of individual particles of spherical form and about 22 mμ in diameter. It readily forms macroscopic crystals, usually octahedra, from aqueous salt solutions. Preliminary X-ray studies indicate that these wet crystals have a large unit cell, and Carlisle suggests[2] that the lattice may be of the diamond type. Attempts have been made to obtain replicas of the dry crystals, by the method which has proved successful with some other plant viruses[3,4], but these have not shown any regular structure. The failure may be due to the shape of the crystals or to difficulties of drying.

Electron micrographs have been taken (by transmission) of the virus mounted on beryllium films, and some of them show a number of micro-crystals having the appearance of a net formed by hexagonal rings (Fig. 1). Each ring has an electron-transparent hole in the centre, of such a size that the rings appear larger than the size of the individual virus particles. From the photographic density of the images, it may be estimated that the crystalline fragments are only a few molecules thick in the direction of the electron beam. The fainter patches in the background also show similar structure in some regions, and may be only two or three molecules deep.

As the electron micrographs seemed to agree with a diamond-type lattice, measurements were made on the hexagonal network in various directions. The

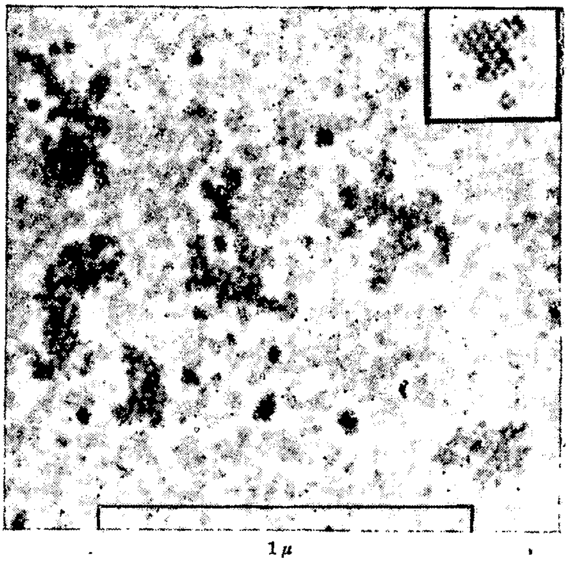

Fig. 1. ELECTRON MICROGRAPH OF FRAGMENTS OF CRYSTALLINE TURNIP YELLOW MOSAIC VIRUS: PHOTOGRAPHED AT 19,000×, TOTAL MAGNIFICATION 48,400×. INSET: OUT-OF-FOCUS PHOTOGRAPH OF MODEL OF DIAMOND LATTICE

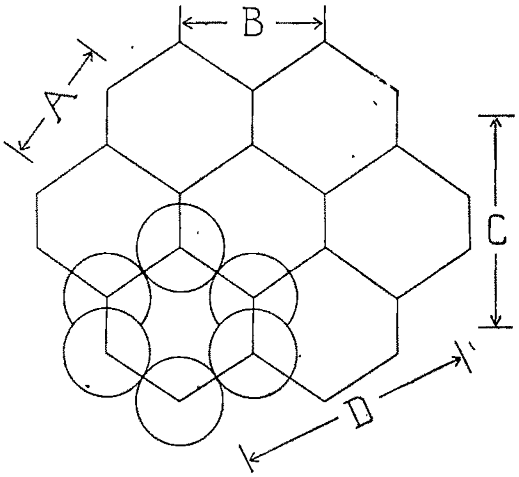

Fig. 2. PROJECTION OF DIAMOND-TYPE LATTICE, VIEWED NORMAL TO 110 FACE

measurements were made easier by the fact that the crystalline regularity extended in places as far as 150 mμ, although in other places there was obvious distortion. Prints of the negatives were made on process plates, and these were projected at a final magnification of 186,500 times on to paper. The centres of the holes were marked, and measurements made with a ruler, the distances between 146 pairs of holes being measured in all. The measurements were made in four principal directions inclined to each other (*A*, *B*, *C*, *D*, in Fig. 2), and suggest that the pattern is not a regular hexagonal one, since for the latter $A = B$ and $C = D$. They do, however, agree well with the hypothesis that the crystal is of diamond type, viewed normal to the 110 face, along the diad axis. The measurements are tabulated in Table 1.

TABLE 1

Axis	Average distance (mm.)	No. of holes measured
A	5·18	42
B	5·40	56
C	8·60	35
D	9·67	13

From the known relative values for the dimensions *A*, *B*, *C* and *D*, the theoretical spacings fitting the above data were calculated by the least squares method and are given in Table 2 in units of the diameter of the particles composing the lattice, assuming them to be rigid spheres.

TABLE 2

Axis	Theoretical value	Value calculated from experimental data
A	1·41	1·44
B	1·63	1·50
C	2·31	2·40
D	2·74	2·70

A photograph of a model of the diamond lattice, taken out of focus to correspond with the lack of resolution of the electron micrograph, has been superimposed on Fig. 1 in order to give a visual comparison of the observed and postulated structures.

The size of the rigid spherical particle best fitting the data is 19·5 mμ in diameter. As the dry virus has a density of 1·45, the molecular weight is about $3{\cdot}5 \times 10^6$. These figures compare with the value of 22 mμ for the diameter, obtained from electron micrographs of individual dry particles and by other methods[5], and with the value of 30 mμ suggested by the X-ray evidence and 28 mμ from the diffusion constant, the latter two values referring to the particles in the wet state. On the basis of these values, the water content by volume of the crystals would be 84 per cent, compared with 62 per cent for bushy stunt virus crystals. However, the formation of a diamond-type lattice, instead of a close-packed type, by the turnip yellow mosaic virus would indicate the existence of tetrahedrally directed bonding forces between the virus particles. It is therefore possible that in the crystal the particles suffer distortion compared with the spherical form which they probably (although not certainly) have in isolation. Such a change in shape in the lattice would allow a smaller water content than that derived on the assumption of rigid spheres.

The beryllium films were prepared according to the method described by Hast[6]. One droplet of the virus suspension in distilled water is placed on a collodion film carried on a nickel specimen grid. After drying, a layer of beryllium approximately 50 A. thick is evaporated on to the surface in a highly evacuated bell-jar. Immersion in pure amyl acetate or acetone dissolves away the underlying collodion, leaving the virus supported by the beryllium alone on the nickel grid. The original micrographs were taken at a magnification of 15,000.

Attempts to observe similar crystals by drying the virus on pre-formed films of beryllium have so far yielded no unambiguous result, although fragments of the same general shape as shown in Fig. 1 are frequently obtained; they are, however, not resolved into molecular structure. It is probable that the evaporation method of making the beryllium film results in an accentuation of contrast in the specimen, the deposited film having a slightly greater thickness to the beam where it is inclined to the plane of the collodion substrate; a similar effect gives rise to contrast in silica replicas of surfaces. It may also be that beryllium atoms reaching the surface are mobile on it for a short while, and aggregate preferentially along edges. Similar preparations of tomato aucuba mosaic virus show such an accentuation of the sides of rods and rod-aggregates (Fig. 3). When this virus is settled on to preformed beryllium films, however, no

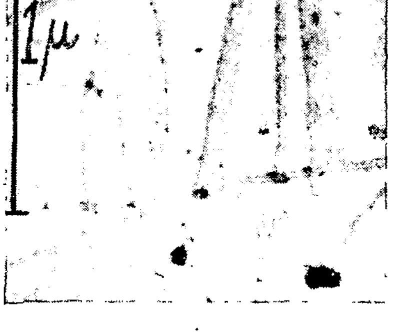

Fig. 3. ELECTRON MICROGRAPH OF TOMATO AUCUBA MOSAIC VIRUS PARTICLES ON BERYLLIUM SUPPORTING FILM: PHOTOGRAPHED AT 16,000 ×, TOTAL MAGNIFICATION 51,000 ×

trace is visible of this effect, making it clear that the particles are not hollow in the centre, as might be inferred from Fig. 3.

Beryllium films allow much clearer micrographs to be obtained of virus and similar particles than when they are carried on collodion films, owing to the greater background scattering given by the latter. Particle-size determination is thereby made more accurate, especially when side-by-side aggregations are obtainable, as in Fig. 3. It is observed, however, that the virus exposed to the electron beam rapidly becomes clouded over and all definition is lost in a few minutes. It is probably as much due to this effect as to the greater background scattering, that the lattice structure in crystalline fragments of viruses has not previously been observed with collodion-supported preparations. The nature of this contamination has been discussed elsewhere[7].

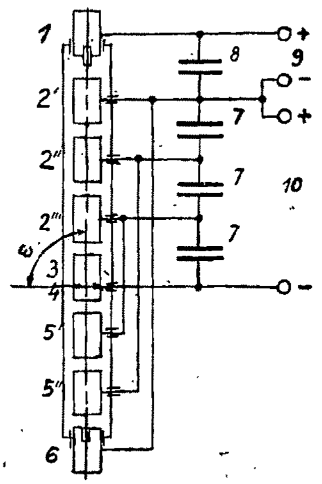
DISCHARGE TUBE FOR NUCLEAR REACTIONS WITH IMPROVED YIELD

In an article on a "Discharge Tube for Nuclear Reactions with Improved Yield" (*Elektrotechnický Obzor* (Prague), 36, No. 14, 266; 1947), I have described a new discharge tube which, besides giving a better yield and minimized target heating, has the advantage that the acceleration of the particles is effected in two stages: acceleration by means of 100–300 kV. with a current consumption of the order usual for normal discharge tubes using 1–2 MV., and a following principal acceleration by a tension of some megavolts with a current consumption less than five hundredth of usual values.

As shown in the accompanying diagram, particles leaving the ion source 1 are subjected to the first acceleration before the electrode 2, and then they are highly accelerated between the electrodes 2′, 2″; 2″, 2‴; 2‴, 3. The highly accelerated particles go through the target, which is 5 × 10^{-4} cm. thick. Only a small number of them produce nuclear reactions or are diverted from their direct paths. Through the scattering by electrons, the other particles give up that part of their kinetic energy which they have obtained by the first acceleration, and thus heat the target. Then they are retarded into the electrostatic field between the electrodes 3, 5′; 5′, 5″; 5″, 6 to such a degree that they enter into the recombination place 6 with little kinetic energy. After recombination, they are sucked from 6 by a high-vacuum pump into a reservoir or through a high-vacuum pipe of sufficient length back into the ion-source 1. The condensers 7 serve to divide the tension. At the same time they hold it constant, as does condenser 8. The tension for the first acceleration is brought to connectors 9 and that for the chief acceleration to connectors 10.



The greater part of my article relates to the theoretical calculations of the energy conditions in the new tube, and six numerical examples are provided. In order to produce 10^{11} neutrons per second from beryllium 5 × 10^{-4} cm. thick by deuterons, we need for the first acceleration the current-intensity 800μA. at a tension of 300 kV., and for the chief acceleration 0·28μA. at 2·70 MV. If we raise the tension for the chief acceleration to 9·90 MV., the current consumption is 0·016μA. for the chief acceleration and 800μA. at a tension 100 kV. for the first acceleration. In the usual discharge tubes with a massive target, we need under the same conditions a current intensity not less than 150μA. at 3 MV. and not less than 16μA. at 10 MV.

Thus the reduction of current consumption for the chief acceleration is very considerable. Also the target heating is minimized. In spite of this, its cooling (by radiation) is the most difficult problem of the new tube. This point will probably decide whether it will be advantageous to construct the tube.

The principal idea of the new tube, namely, to regain the kinetic energy of the highly accelerated particles by means of retardation in the electrostatic field, can be used with great advantage in the construction of other tubes for nuclear physics. In those, and not in the tube discussed, lies the practical use and importance of the scheme.

Jaroslav Pachner

WAR-TIME RHEOLOGICAL INVESTIGATIONS FOR THE BRITISH ARMED SERVICES

A GENERAL meeting of the British Rheologists Club was held at the Royal Society of Arts o December 17, when papers on war-time rheologica investigations were read by Dr. A. S. C. Lawrenc (Navy), Mr. A. G. Ward (Army) and Dr. E. W. J Mardles (Royal Air Force). Dr. A. S. C. Lawrenc spoke on the experiments done subsequent to th lecture on rheology and Naval problems by Si Charles Goodeve in 1943 ("Essays in Rheology" Pitman, 1947), and by means of photographs h described the icing of ships in the North Atlanti and methods employed for de-icing. Dr. Lawrenc continued with the problem of sea-water – fu emulsions and fundamental work carried out in con nexion with it.

Mr. A. G. Ward spoke on researches carried ou with regard to the elasticity and plasticity characte istics of various propellants and of methods of rhe logical measurement involved, including those resonance and penetration. Dr. E. W. J. Mardle mentioned rheological problems involved in the hig speed and high-altitude flight of aircraft, when ten peratures so low as – 80° C. are sometimes reache with consequent development of tendency materials to fracture. Methods of measurement of the consistency of greases and lubricants at low temperatures had been worked out and were briefly described.

Mr. A. de Waele (in the chair), in opening the discussion, remarked on the wide range of problems dealt with successfully by the rheologist; among the subjects discussed by the meeting were the dispersion phenomena of cellulose derivatives in organic media, the movement of spheres in emulsions and non-Newtonian liquids in general (Stokes' law is not usually applicable), rigidity-thixotropy, and the penetration of clays and other soft solids by piles and other penetrometers. Dr. A. W. Skempton described some recent experiments on clay movement, supporting the findings of A. S. C. Lawrence that the movement of a droplet in a fuel – sea-water emulsion is accompanied by vortex movement extending to at least ten diameters, and of E. W. J. Mardles that similar movements have been observed in thickened liquids during penetration by spheres, disks, rods or cones. The general movement over a wide range of the system, such as when a grease is penetrated by a solid body, may account for the finding of E. W. J. Mardles that the volume displaced by a penetrometer of given weight over a period of time is more or less independent of the shape, and characteristic of the material.

SOCIAL STUDIES OF THE ELDERLY

By ELEANOR FRENCH

IT is interesting to watch the emphasis slowly shifting in the sphere of social welfare to the elderly and their needs and problems, as the relentless march of time forces the effects of our ageing population upon our notice. In 1901 there were 2,408,426 persons in Great Britain over sixty years of age; in 1946 there were 6,587,000 [1], and the assumption in the Beveridge Report is that by 1971 there will be 9,576,000 men over sixty-five and women over sixty in Britain[2].

The two extremes of life thus assume a new importance, and the increasing claims of the ageing must not be met at the expense of the young; but to say this does not mean that those claims should be ignored. The publication of "Old People" by the Trustees of the Nuffield Foundation[3] earlier in the year aroused much interest; this has been followed by a further survey of a particular district: "Old People's Welfare on Merseyside"[4], and in June the British Medical Association published a report on the care and treatment of the elderly and infirm. These three documents give a clear picture of the present conditions in which the elderly are living and make recommendations for improving and supplementing them.

One of the most urgent needs for them (as for everyone else) is better housing: there appears to be little question that old people are badly underhoused, and according to Dr. Elsas[5], in 1939, given a ratio of forty dwellings per hundred adults, the 3·7 million persons over sixty-five should have had 1·5 million dwellings; but there were actually at that time only half a million dwellings in England and Wales consisting of one or two rooms. Conditions have certainly not improved since then, and the Nuffield Survey[3] recommends "that 5% of the houses in any community should be such as are suited to the special needs of old people. . . ."

But though 95 per cent of old people live in private houses[3], the remaining 5 per cent live in institutions, whether public or private, and here, too, conditions are often unsatisfactory. 'Institutions under the local authority are often vast old-fashioned 'barracks': for example, in four of these institutions in Liverpool and Birkenhead on one night in February 1946 there were 2,312 [4] old people of pensionable age: "The sight of a dining room seating 300, a huge dormitory with 110 beds . . . is most depressing"[4]. Old people and children seem to need very similar conditions for their welfare and happiness, and the Report of the Curtis Committee regards large institutions as quite unsuitable for young children also. It is good news that local authorities, or rather 'welfare authorities' as they will be called, have been given power to establish special homes for the aged to house between twenty and thirty.

Adequate medical aids, another pressing want of the aged, will be available under the new National Health Service. When these and other material needs have all been met, there still remain those of the spirit, for old age is apt to bring loneliness, a sense of uselessness, and boredom. Much could be done to remedy these: Dr. Vischer, for example, at Basel, has his homes for the aged attached to the municipal hospital, and their inmates are offered, if they wish, suitable types of work in the clinics and dispensary, for which they are paid a small fee[6]. Such a scheme encourages the old people and gives them a sense of still being useful members of a community, and at the same time it helps the hospital to solve its staff problem. Old age tends to isolate the individual from the main stream of life, but at the same time full utilization of his remaining powers is needed for the benefit of the community of which the aged form an increasing part.

FUEL ECONOMY IN SWITZERLAND

THE World Power Conference is issuing reports on war-time fuel-saving methods in many States. Obviously these differ widely.

The problem in Switzerland* was given a particular interest by clear-cut circumstances and limitations. That country lacks substantially all native solid or liquid fuel resources except wood, and this plays an insignificant part. The only freely available source is hydro-electric power, and this provides only a minor part of the need. Furthermore, it is essentially seasonal in supply, being dependent on the variable flow of streams. Summer is the principal season for the production of water-power, whereas winter is the time when power is in greatest demand. Available storage facilities are inadequate to compensate for this disparity. At most, available water-power provides for the needs for lighting and motive power, but by no means for heating or the industrial demands for electrothermal and chemical needs.

---

* Reports on Fuel Economy since 1939. Swiss National Committee. Pp. 20. (Central Office of World Power Conference, 201–202 Grand Buildings, Trafalgar Square, London, W.C.2.) 1*s.* net.

The experience of the First World War stimulated the development of hydro-electric resources and the use of electricity for railways, lighting, power and special heating, where it offered a preponderating advantage. It could only be used in summer for general heating and for electrochemical or electrometallurgical purposes. By 1938, 98 per cent of the railway traffic was electrically operated, but electricity provided 5 per cent only of the total supply of thermal energy. Three-quarters of the heat was supplied by imported coal. Moreover, between 1913 and 1938 the consumption of coal altered little. There was only a change in the distribution of the load.

When war broke out in 1939 it was not surprising that rationing became drastic and realistic. All production of electricity by fuel-fired boilers—except back-pressure units—was suspended. Coal was allocated according to priorities. Domestic heating, which in 1938 absorbed 50 per cent of the imports of coal, was 'mercilessly' cut to nil in 1943–44, and gas to 21 per cent in 1945–46. In winter, electricity would be prohibited for space heating, water heating and steam generation, these being termed 'low-efficiency uses' of electricity. Industrial coal-fired boiler plant offered little scope for fuel saving, owing to the high efficiencies current in peace-time. To meet the high cost of fuel, boiler efficiencies of 75–80 per cent were the rule, even in small plants. Figures such as these are uncommon in Great Britain.

In conclusion, the report says that in spite of the abundance of water-power, half of which is already developed, Switzerland remains dependent on imported coal. There need be no illusions of its replacement by hydro-electric power. The supply of electricity is limited by natural causes. Its proper application is the supply of power, and in winter its use for low-grade heating is not encouraged.

NEW ITALIAN COSMIC RAY LABORATORY

A NEW high-altitude research laboratory for cosmic ray work at a height of 11,500 ft. on the upper slopes of Monte Rosa was opened by the Italian Centre for Research in Nuclear Studies on January 11. The laboratory portion of the station at present consists of one large experimental room, and a small fully screened room for a Wilson cloud chamber. The equipment is very complete, and includes a three-phase 30 kW. power supply, a separate lighting supply, and two high-capacity battery sets with a petrol generator in case of main power failure. The station is also equipped for two-way direct radio contact with the parent laboratory at Rome, a useful facility at all times, but particularly necessary when the Laboratory is likely to be cut off from the outside world for days at a time in mid-winter.

The Laboratory is situated on an exposed ridge on the Italo-Swiss frontier, and is actually half in Switzerland. It is served by a cable railway, which—under normal weather conditions—runs from Breuil (Cervinia) in the valley, 4,500 ft. below. Breuil is itself connected with the rail-head at Chatillon by a road which is kept open throughout the winter. The problems of supply are, therefore, very much less than might reasonably be expected at such an altitude.

At the present moment, the Laboratory has living accommodation for four workers, with bunks, a small kitchen and bathroom. Water is obtained by melting snow with an immersion heater, the water then being pumped to a roof-tank. Waste disposal is by a double-walled heated pipe. The building itself is of aluminium and cork construction, and is securely anchored against the high winds which sweep the ridge.

The work at present going on in the Laboratory includes the exposure of nuclear plates, which in suitable weather can also be carried out up to 3,000 ft. above the Laboratory. Experiments on meson decay are also being carried on, and it is expected that later some Italian geneticists will be undertaking work at the station on mutations induced by cosmic rays. The director of the Laboratory is Prof. Gilberto Bernadini, who, with the director of the Centre for Research in Nuclear Studies, Prof. Edoardo Amaldi, is already well known in Britain for his work in this field. It is expected that at least one British physicist will be working at the Laboratory in the near future.

The inauguration ceremony was performed by Minister of the Treasury, Del Vecchio, in the presence of some sixty distinguished Italian scientific workers, and representatives of various industrial firms and the Italian Air Ministry. At the invitation of Profs. Bernadini and Amaldi, British science was represented by Dr. Tahourdin, science officer in Italy of the British Council.

VETERINARY EDUCATIONAL TRUST

THE Veterinary Educational Trust was formed in 1942, to provide for the education of graduate and postgraduate students of the best type who would not otherwise be able to proceed with their studies; means were to be found to ensure that training was provided of a type not otherwise available in Great Britain, so that veterinarians and other men of science would be equipped to undertake original research.

In the course of the ensuing years, it has been found that the original aims require to be extended. It has been decided to embark upon a plan to develop research stations dealing with the management and diseases of the different species of domesticated animals. An Equine Research Station at Balaton Lodge and Lanwades Park near Newmarket (director, Prof. W. C. Miller), a Canine Research Station (director, Mr. S. F. J. Hodgman), and also a Poultry Research Station (director, Dr. R. F. Gordon) have been opened; all these directors are veterinary surgeons.

A group of farm livestock research stations will be opened; negotiations are in progress for sites for such work. All these stations will be established within a few miles of each other and of the University of Cambridge. In developing these centres, care is being taken to ensure that there is close contact between them and the workers in the field, and there will be close co-operation with practising veterinary surgeons. The research stations will link up with a series of hospitals for large and small animals, and there will be joint laboratory diagnostic service. The aim will be to have a hospital in every county and in the larger towns.

Modern veterinary hospitals require elaborate design and equipment and cannot usually be provided by the private practitioner. Under the schemes now envisaged, they will be managed in such a way that whole-time staffs are available, and private practitioners and specialists will co-operate in the care of the patients. At the same time, the aim is to organise cadres of trained animal nurses and technical assistants, probably coupled with a system of training, certification and registration.

Since the Trust was inaugurated in 1942, forty-eight undergraduates have been awarded scholarships or studentships in the United Kingdom and Eire. Deserving students who are well embarked on their studies, but have suffered an adverse change in their financial circumstances and, otherwise, would have been unable to proceed with their studies, have been assured an opportunity of obtaining their qualifications. £7,320 has been expended on the assistance of such students. In addition, nineteen Evans Final Year Studentships have been awarded to the best students in the previous four years of study at the respective veterinary colleges.

The Wellcome Trust, the Goldsmiths Company, Messrs. Cooper, McDougall and Robertson, Ltd., the British Oil and Cake Mills, Ltd., and Imperial Chemical Industries, Ltd., have provided funds for research fellowships held under the Trust. Details have been given of eleven such fellowships now held by British veterinary and other science graduates for studies of a very varied nature at scientific institutions in the United Kingdom and the United States of America.

At the annual general meeting of the Trust, held in October 1947, a detailed account of progress was given. It was attended by an influential body of people, including, in addition to the officers of the Trust, senior representatives of the livestock and other interests concerned, such as the secretary of the Agricultural Research Council, the president of the Royal Agricultural Society of England, the president of the Royal College of Veterinary Surgeons, the president of the National Veterinary Medical Association of Great Britain and Ireland, and many others. Influential committees have been appointed to cover the several special interests concerned. The Duke of Norfolk is president and the Duke of Beaufort is the honorary treasurer. Dr. W. R. Wooldridge is the scientific director. The income for the year ended August 31, 1946, was £39,240 and the expenditure was £21,558. The assets amounted to £137,410, with a mortgage of £20,000 on property held.

Complementary to the scientific, educational and other activities, an organisation is being developed for acquainting the public throughout the country with what is being done and for collecting the money required for the operations of the Trust, the address of which is 232–35 Abbey House, Victoria Street, London, S.W.1.

VEGETABLE TANNING MATERIALS OF INDIA

THE Forest Research Institute at Dehra Dun has issued a series of Forest Leaflets dealing with the vegetable tanning materials of India (Nos. 72, 73, 74, 75 and 76, published in 1944–45).

Leaflet No. 72 dealt with a general survey of the vegetable tanning materials of India (Part 1); No. 73 with the same heading (Part 2), the tanning materials of *avaram* (*Cassia auriculata*); No. 75, the tanning materials obtained from the well-known Myrobalan (*Terminalia chebula*).

In Leaflet No. 74 (Civil and Military Press, Prem Nagar, Dehra Dun, 1945) the tree dealt with is the *Acacia arabica*, the best-known vernacular names of which are *babul*, *kikar* and *babar*. The tree has several varieties. The information given deals with the bark and the pods, their tanning content and its variation with age, part of the plant from which obtained, and the locality of its tree growth. Information is also given on the yield obtained from the bark and the pods, the quantities of bark used and its origin and price, the methods of collection and preparation for the market; the tanning properties and manufacture of the extract are also discussed.

Some data interesting to the forester are given with reference to the sylviculture of this tree, and the use of the bark and the timber are briefly dealt with. For a long period babul bark was one of the most firmly established tanning materials of India. It is now said to be losing its ground owing to two factors: it is not marketed as satisfactorily as its chief competitor, wattle bark, and there has been a failure in replacing by replanting trees as fast as they have been felled. Investigations on a wider scale are being carried on into some of these points.

In Leaflet No. 76, the black wattle (*Acacia molissima*) is discussed, with notes on other wattles growing in India, and their tanning content. In view of the remarks already made about *Acacia arabica*, this leaflet affords some valuable indications from various analyses made, such as variations in tanning content and, for black wattle, the yield of bark in South Africa and Java and the probable yield in India. Methods of collection and preparation for the market, tanning properties and manufacture of the extract are dealt with, and statistics of South African production, Indian imports and prices, and world use of wattle and other tanning materials are given. It is concluded that Indian-grown wattle could be made of equal tanning value to the South African bark, but more research is necessary.

The value of these researches into vegetable tanning materials is of obvious importance, since there are those who consider that this type of tanning material will always be superior to the chemical tannings.

Monday, February 16

EUGENICS SOCIETY (at Manson House, 26 Portland Place, London, W.1), at 5 p.m.—Mr. W. Russell Brain: "Some Reflections on Genius" (Galton Lecture for 1948).*

ROYAL PHYSICAL SOCIETY OF EDINBURGH (at the Royal Scottish Geographical Society, Synod Hall, Castle Terrace, Edinburgh), at 5.15 p.m.—Prof. C. H. Waddington, F.R.S.: "Animal Development".

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY (at the University, Manchester), at 5.30 p.m.—Prof. R. E. Lane: "National Industrial Life and the Doctor" (Percival Lecture).*

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at the Royal Institution, Albemarle Street, London, W.1), at 6.30 p.m.—Mr. H. W. Cremer: "Water, a National Asset" (Jubilee Memorial Lecture).

Tuesday, February 17

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP (joint meeting with the MANCHESTER SECTIONS of the SOCIETY OF CHEMICAL INDUSTRY and the ROYAL INSTITUTE OF CHEMISTRY, at the Gas Showrooms, Town Hall Annexe, Manchester), at 10 a.m.—Opening by Dr. Norman C. Wright of the Ministry of Food B.I.O.S. Exhibition; at 10.30 a.m.—Mr. F. C. White: "New Developments in the German Dairy Industry"; Mr. H. J. Bunker: "Wartime Production of Food Yeast in Germany"; at 2.30 p.m.—Mr. J. F. Hearne: "German Albumen Substitutes"; Mr. R. Perdue: "German Soapless Detergents".

Royal Society of Arts, Dominions and Colonies Section (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Mr. C. B. Symes: "Control of Insect-borne Diseases in the Colonies—Some Recent Progress and Future Prospects".

Society of Chemical Industry, Agriculture Group (in the Chemistry Department, Royal College of Science, Imperial Institute Road, London, S.W.7), at 2.30 p.m.—Prof. T. Wallace: "Methods of Determining Mineral Deficiencies in Plants"; Dr. D. J. D. Nicholas: "Chemical Tissue Tests for the Determination of Mineral Status of Plants".*

Royal Anthropological Institute (at 21 Bedford Square, London, W.C.1), at 5 p.m.—Dr. A. E. Mourant: "The Use of Blood Groups in Ethnology".

Institution of Civil Engineers (at Great George Street, London, S.W.1), at 5.30 p.m.—Mr. B. D. Richards: "Tidal Power, its Development and Utilization".

Conway Discussion Circle (at Conway Hall, Red Lion Square, London, W.C.1), at 7 p.m.—Dr. Meyer Fortes: "The Social Basis of Primitive Religion".*

Royal Photographic Society, Scientific and Technical Group (at 16 Prince's Gate, London, S.W.7), at 7 p.m.—Mr. G. S. Moore: "The Last Ounce of Speed".

Institution of the Rubber Industry (at Caxton Hall, Caxton Street, London, S.W.1).—Symposium on "Latex".

Wednesday, February 18

British Society of Animal Production (at the Royal Agricultural Society of England, 16 Bedford Square, London, W.C.1), at 10.15 a.m.—Annual General Meeting; General Topic: "Animals and Grass".

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Dr. Sutcliffe, Mr. Priestley and Dr. Sawyer: "The Mechanics of Weather Systems".

Royal Microscopical Society (in the Hastings Hall, B.M.A. House, Tavistock Square, London, W.C.1), at 5 p.m.—Mr. Frank Baker: "Scope and Applications of Direct Microscopy to the Investigation of Starch and Cellulose Breakdown in the Digestive Tract".

Oil and Colour Chemists' Association, London Section (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Dr. A. W. Johnson: "Synthesis from the Acetylenes, including Methods of Making Vinyl and other Polymer Resins".*

Thursday, February 19

University College London (in the Anatomy Theatre, Gower Street, London, W.C.1), at 1.15 p.m.—Dr. Kathleen Lonsdale, F.R.S.: "The Structure of Solids".*

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Dr. A. R. Clapham and Dr. H. Godwin, F.R.S.: "Studies of the Post-Glacial History of British Vegetation", Parts 8–10.

Institution of Mining and Metallurgy (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. Walter Frayne: "The Development and Introduction of a New Process for the Economic Recovery of Minute Quantities of Gold from Lead-Silver Bullion derived from the Bawdwin Ores"; Mr. A. L. Austen: "Notes on Labour Organisation and Performance at the Badhia Mine, Indian Copper Corporation, Ltd.".

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. A. E. Taylor: "Banach Spaces of Functions Analytic in the Unit Circle".

Chemical Society (in the Chemistry Lecture Theatre, University College, Nottingham), at 6 p.m.—Dr. E. R. H. Jones: "Synthesis in the Vitamin A Field".

Chemical Society (joint meeting with the Hull and District Section of the Royal Institute of Chemistry and the University College Scientific Society, in the University College, Hull), at 6 p.m.—Prof. E. G. Cox: "The Optical Properties of Molecules".

Chemical Society (at Burlington House, Piccadilly, London, W.1) at 7.30 p.m.—Sir Edward Mellanby, K.C.B., F.R.S.: Sir Frederick Gowland Hopkins Memorial Lecture.

Royal Society of Tropical Medicine and Hygiene (at Manson House, 26 Portland Place, London, W.1), at 7.30 p.m.—Prof. B. G. Maegraith: "The Pathological Processes in Malaria"; Dr. W. H. H. Andrews: "Liver Lesions in Malaria".

Friday, February 20

Institute of Navigation (at the Royal Geographical Society Kensington Gore, London, S.W.7), at 5.30 p.m.—Lieut. P. G. Satow: "Radar and the Weather—Problems in Marine Navigation".

Institution of Electrical Engineers, Measurements Section (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Dr. E. Bradshaw, Mr. S. A. Husain, Mr. N. Kesavamurthy and Mr. K. B. Menon: "Absolute Measurement of High Voltages by Oscillating Electrode Systems".

Institution of Mechanical Engineers (joint meeting with the Institution of Electrical Engineers, at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Mr. J. R. Rylands and Mr. J. R. Jenkinson: "Corrosion of Heating Surfaces".

Manchester Statistical Society, Statistical Methods Study Group (at the Society of Architects, 16 St. Mary's Parsonage, Manchester), at 5.45 p.m.—Mr. J. A. Hough: "An Analysis of Co-operative Statistics".

North-East Coast Institution of Engineers and Shipbuilders (at the Mining Institute, Newcastle-upon-Tyne), at 6.15 p.m.—Mr. R. G. Manley: "The Analysis and Interpretation of Vibration Records and similar Traces in Engineering"; Dr. F. H. Todd and Mr. W. J. Marwood: "Ship Vibration".

Society of Engineers (at 17 Victoria Street, London, S.W.1), at 6.30 p.m.—Mr. L. J. Merry: "Technical Education".

Institute of Industrial Administration, Manchester Centre (in the Reynolds Hall, College of Technology, Manchester), at 7 p.m.—Mr. G. Cheliotí: "Management and Research".

Paper Makers' Association (Technical Section), Northern Division (at the Engineers' Club, Albert Square, Manchester), at 7 p.m.—Dr. Julius Grant: "Some New View-points on the Problem of Pulp and Paper Mill Effluents".

Textile Institute, Dublin Section (at the Mansion House, Dublin), at 7.30 p.m.—Mr. A. Nisbet: "Emulsions and their Use in the Textile Industry".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. C. E. Raven: "Some Neglected Aspects of the History of Science".

Saturday, February 21

Institution of Chemical Engineers, North-Western Branch (in the Reynolds Hall, College of Technology, Manchester), at 3 p.m.—Mr. P. Hamer: "Water Treatment".

Manchester Literary and Philosophical Society, Social Philosophy Section (at the Portico Library, 57 Mosley Street, Manchester), at 5.30 p.m.—Prof. D. M. Mackinnon: "The Moral Implication of the Atomic Bomb".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Laboratory Technician to Hospital Physicist—The Secretary, University College Hospital, Gower Street, London, W.C.1 (February 21).

Chief Technician—The Director, South London Blood Supply Depot, Benhill Avenue, Sutton, Surrey (February 21).

Demonstrator in Anatomy—The Registrar, The University, Sheffield (February 21).

Agricultural Economist in the Department of Agriculture and Lands, Southern Rhodesia—The Secretary, Office of the High Commissioner for Southern Rhodesia, 429 Strand, London, W.C.2 (February 27).

Lecturer (experience in Stratigraphy or Applied Geology desirable) and Assistant Lecturers (2) in Geology, Lecturers (2) and an Assistant Lecturer in Geography, a Lecturer in Social Psychology, and a Lecturer in Moral Philosophy—The Secretary of University Court, The University, Glasgow (March 1).

Assistant Lecturer in Mycology—The Registrar, The University, Manchester 13 (March 6).

Petrologist on the Geological Survey of the Gold Coast—The Director of Recruitment (Colonial Service), 15 Victoria Street, London, S.W.1 (March 8).

Chair of Psychology—The Secretary of University Court, The University, Glasgow (March 11).

Cytologist (Scientific Officer grade)—The Director, Welsh Plant Breeding Station, Agricultural Research Building, Penglais, Aberystwyth (March 13).

Analytical Chemist, and a Geologist, in the Department of Geological Survey, Southern Rhodesia—The Secretary, Office of the High Commissioner for Southern Rhodesia, 429 Strand, London, W.C.2 (March 15).

Lecturer and an Assistant Lecturer with qualifications in Pure Mathematics, a Lecturer and an Assistant Lecturer with qualifications in Applied Mathematics or Mathematical Physics—The Registrar, The University, Manchester 13 (March 15).

Senior Scientific Officers (about 30) and Scientific Officers (about 170) in Government Departments—The Secretary, Civil Service Commission, Scientific Branch, 27 Grosvenor Square, London, S.W.1, quoting No. 2114 (March 15).

Studentships at a British University in preparation for Field Research in one of the Social Sciences in the Colonial Empire—The Secretary, Colonial Social Science Research Council, Palace Chambers, Bridge Street, London, S.W.1 (March 31).

Director of Meteorological Services in the Department of Transport, Pretoria—The Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, London, W.C.2 (March 31).

Chair of Geology at King's College, Newcastle-upon-Tyne—The Registrar, University Office, 46 North Bailey, Durham (April 3).

Professor in charge of the School of Social Work, Victoria University College, New Zealand—The Secretary, Universities Bureau of the British Empire, 8 Park Street, London, W.1 (April 17).

I.C.I. Fellowships for research in chemistry, physics, and allied subjects—The Registrar, The University, Manchester 13 (April 30).

Turner and Newall Fellowships for research in engineering, inorganic chemistry, physics, and allied subjects—The Registrar, The University, Manchester 13 (April 30).

Chair of Organic Chemistry—The Registrar, The University, Sydney, Australia (May 31).

Analytical Chemist at the Tung Experimental Station, Nyasaland—The Director of Recruitment (Colonial Service), Colonial Office, 15 Victoria Street, London, S.W.1.

Senior Technician in the Department of Industrial Metallurgy—The Professor of Industrial Metallurgy, The University, Edgbaston, Birmingham 15.

Good Instrument Maker (Ref. Chemistry/2), and a Technician with knowledge of electricity (Ref. Chemistry/3), in the Department of Chemistry—The Secretary, University College London, Gower Street, London, W.C.1.

Research Fellowship for advanced archæological research in Turkey—The Hon. Secretary, British Institute of Archæology at Ankara, c/o Institute of Archæology, Inner Circle, Regent's Park, London, N.W.1.

UNIVERSITY REPRESENTATION IN THE HOUSE OF COMMONS

BY the terms of the Representation of the People Bill now before Parliament, it is proposed that parliamentary representation shall be limited solely to county and borough constituencies, each returning a single member; and that residence shall be the qualification for the franchise, with the usual conditions that electors must be British subjects of full age and not subject to any legal incapacity to vote. Hence the university constituencies would be abolished.

For some generations, there has not been any kind of redistribution of seats in the House of Commons, much less of redistribution by way of destroying one kind of seat, without preliminary attempts to find the maximum agreement. On this occasion there has been a Speaker's Conference, which recommended, without a dissentient voice, the retention of the university seats. Although all the supporters of the single transferable vote agreed that it was not applicable to constituencies with less than three members, yet it was preserved for the two-member university seats precisely to make it plain that it was desired to give the second largest party among university voters every possible advantage. So recently as October 1947, the present Lord Chancellor, when promising a Bill for electoral reform arising out of the recommendations of the Committee of Electoral Registration, the Speaker's Conference, and the Committee on Electoral Law Reform, proclaimed that if his questioner was familiar with all the proceedings in those Committees, he would be able to forecast precisely what the Bill was going to do. It is difficult to see how Speakers' Conferences can in future be as friendly and non-partisan as they have not unsuccessfully striven to be in the past, if now those parts of the last Conference's recommendation which seem electorally damaging to the present majority in the House of Commons are to be treated so cavalierly.

University constituencies have existed in Britain for about a dozen generations; there is a vague pre-history even older than that. For what antiquity is worth, therefore, they have a title to consideration. Of something the same nature is the argument that university parliamentary representatives are now all that is left to keep alive the old principle of representing corporations. It was the rural corporations which were counties, and the urban corporations which were boroughs, that were represented in the old House of Commons; and to them James I added the 'learned corporations', that is, the universities.

Looking down the list of those who have represented, for example, the University of Cambridge, it is easy to pick out distinguished names. Very early, Cambridge elected Francis Bacon. John Coke, Thomas Eden, a couple of Cromwells, George Thurloe, George Monk followed within half a century; and in the next generation, Sir William Temple, Sir Isaac Newton, and others scarcely less memorable. In the eighteenth century, a very high proportion indeed of the Cambridge men were lawyers of the highest distinction. Towards the end of that century, William Pitt long sat for the University, and after him there were Palmerston, Copley (Lord Lyndhurst), Speaker Manners-Sutton, and others who held high office as ministers or judges, or were men of eminence in more purely intellectual fields. The Oxford list also includes many distinguished names; and the other universities represented in Parliament have, considering the relative lateness of their entry into the field, a scarcely less significant record of service in the House of Commons.

The arguments against university representation can be reduced to two only. One is that it produces members whom the objector dislikes on personal or political grounds. This argument could be valid only if it be agreed that the members elected have been such as the House of Commons would have been better without. The many distinguished men, and more recently women, who have entered Parliament as members for the universities provide sufficient answer to this; it can scarcely be questioned that the House of Commons would have been much the poorer without them.

The other argument used against university representation is that it interferes with strict arithmetical proportion between the House of Commons and the voting public. But does anyone take this principle seriously in these times? It is generally admitted that from the arithmetical point of view Scotland and Wales are properly over-represented, and should continue to be over-represented, in virtue of their national and historical significance. (Incidentally, a similar argument might well save the City of London, which is also threatened with the loss of its representatives.) It is agreed also that the difficulty of representing remote and thinly populated districts is such that they ought to have more members than arithmetical justice would confer upon them; and accordingly, as the House of Commons is at present constituted, and as the Bill now before the House proposes to reconstitute it, there is variation of the number of constituents needed to return a member, in accordance with remoteness from London and with excessive area. Indeed, anyone who really thinks the purely arithmetical principle the necessary dominant in the question is almost driven to proportional representation, with large numbers of seats per constituency, say six or seven, and to annual parliaments, if not to the right of recall by electors.

University members hold less than 2 per cent of the seats in the House of Commons, and nobody suggests that they should hold more. In the two- and three-member university seats, election is by a kind of proportional representation which gives special advantage to the second largest party. It is not reasonable to suggest that any great section of opinion need despair of carrying a university seat, unless it has a very remarkable faculty for antagonizing university graduates. Indeed, there has been no attempt to organise university representation in a tightly partisan way. Any such attempt would almost certainly be doomed to defeat by opinion among graduates, and also, as already indicated, by the method of election in two- and three-member seats.

In any event, it cannot be a bad thing that there should be a few constituencies which are not local, in which the voters are scattered all over the country and indeed all over the world, and in which the rival candidates compete in long, reasoned statements rather than in slogans. *The section of a university constituency resident overseas is a peculiarly important part of the nation. There is little doubt that a very high proportion of British subjects in important posts in Asia and Africa are university graduates. Very many of these men and women have no vote in other constituencies.* A very high proportion indeed of them know their university member, or at least know the sort of man he is, and have friends who do know him directly. There is here a channel of communication between Westminster and Whitehall on one hand, and British subjects serving in public or private posts abroad on the other hand, which has a great and growing value.

The universities of Britain are the highest educational institutions of the country. It is not necessary to think their officers and representatives are over-complacent about them; but they may fairly claim that the universities compare favourably, both in the quality of performance of their function and in public opinion about it, with other great institutions and productive agencies. Yet it is certain that the political and economic tendencies of the last two generations have made it far more difficult for universities and colleges to be independent and self-subsistent than they used to be, and far more difficult also for them to hope for re-endowment from any extra-governmental source. Incidentally, in connexion with Government grants to the universities, it was as well, during the latter years of the War and in the period immediately following, that there should have been men in close touch not only with the leading figures at the universities, but also with Westminster and Whitehall, who preserved a critical faculty about blithe presumptions that in the immediately post-war period there would be, easily and of course, more and better education, with much more money and much more material at its disposal. Surely we are now at a moment when it is peculiarly evident that higher education, and especially the highest education, should have some guarantee of direct two-way communication between the universities and Westminster otherwise than by the relations between the official academic authorities and the Treasury and other Government departments, good and valuable though such relations are. The universities of Britain, as the culminating point of the educational system of the country and also as the symbols of a broad and cultured outlook on human affairs, are likely to increase in importance in the years to come. As such they are entitled to seats in the House of Commons, quite apart from the influence on the course of debate exerted by men of the type sent to Westminster by the universities. No satisfactory case can be made for the abolition of the university franchise.

A SHORT HISTORY OF SCIENCE

The Growth of Physical Science

By Sir James Jeans. Pp. x + 364 + 14 plates. (Cambridge: At the University Press, 1947.) 12*s*. 6*d*. net.

THE reputation of Sir James Jeans as an interpreter of science for the educated layman stands deservedly high. His wide interests and broad sympathies, aided by an exceptional power of exposition and a lucid and dignified prose style, have won him a very considerable circle of readers; and his writings have done much to substantiate the claim that science, in spite of the technicalities with which it is necessarily surrounded, has a cultural value, and some right to be regarded as one of the 'humanities'. The strength of the reaction provoked by his books from the philosophers on one hand and from the upholders of the strictly utilitarian conception of science on the other may be taken as a measure of his achievement.

In "The Growth of Physical Science", his last volume, the proofs of which were revised by him just before his death in September 1946, Sir James Jeans breaks fresh ground. It is true that, in the last chapter, he brings us again to the frontiers of knowledge; but he is, in the main, concerned to trace the long and devious route by which the physical sciences have advanced to their present position. "I have thought," he writes in the preface, "I might usefully try to describe the main lines of advance of physical science, including astronomy and mathematics, but excluding all points and side-issues, in language non-technical enough to be understood by readers who have no scientific attainments or knowledge." The last clause must not be taken too literally. It is, of course, scarcely possible to discuss the history and development of mathematics intelligently without the use of some mathematical symbols and processes. The reader, particularly in the earlier chapters, will find it necessary to evoke some memories of his school 'maths', and may, incidentally, find that subject glowing with an interest it had not awakened before. Nor can the reader "with no scientific attainments" be promised that he will understand every word of the highly condensed account of the era of modern physics contained in the last chapter. He may find himself confessing (like Alice after reading the immortal "Jabberwocky"), "Somehow it seems to fill my head with ideas—only I don't know exactly what they are". Even this degree of apprehension may be well worth-while; it is, after all, with the history rather than the details of scientific discovery that the book is concerned.

It is no easy matter to compress within some three hundred and sixty pages the history of three great sciences; to do full justice to the genius of the ancients, facing absolutely new problems with nothing to guide them, and yet to give due space to the spate of discoveries and theories of modern times; to estimate the relative historical importance, say, of a Pythagoras and an Einstein, of Archimedes and Faraday. In the present volume roughly one third of the space is concerned with classical times, ending with the burning of the library at Alexandria; another third brings us to the end of the age of Newton; leaving some one hundred and thirty pages for the two hundred and fifty years since that date. One cannot help feeling that the pace, towards the end, is becoming a little breathless. No one but Jeans could have condensed so much into so small a space without reducing his text to a mere catalogue; and the book is certainly not that, even when it is most condensed. One can only wish that Sir James, with his wide sympathies and penetrating judgment, had dealt with this final quarter of a millennium more nearly on the scale of the earlier chapters of the book.

Science is an activity of human beings and its progress must be influenced by, and in turn must influence, the religion, the philosophy and the social structure of its age. Any true history of science must take these interactions into account, and Jeans has dealt with them with the objectivity and impartiality which one should expect from a man of science, but which have been conspicuously lacking in some recent popular writings on the subject.

"The Growth of Physical Science", though not altogether free from historical errors, is a very human and a very fascinating volume, which holds the reader like a well-told tale. It is possible that the general diffusion of an understanding of the methods and purpose of science, which all regard as urgent, may be most easily attained through a study of its history. If, as we are told, a study of the past holds the clue to the present, it may be that in the history of science we may find some hints for a solution of some of those vital problems with which the dominance of scientific discovery confronts our civilization to-day.

J. A. Crowther

CALCULUS BASED ON THE FUNDAMENTAL CONCEPT OF NUMBER

Differential and Integral Calculus

Functions of One Variable. By Prof. Francis D. Murnaghan. Pp. x + 502. (Brooklyn: Remsen Press, 1947.) n.p.

In the evolution of the teaching of mathematics, many thoughtful teachers frequently examine critically the basic concepts of the subject in order to make quite sure that the edifice they are constructing is sound and stable. As Prof. Bell[1] points out: it may seem strange "to build up vast systems of knowledge without seeing first whether the foundations will bear the superstructure, and mathematics did precisely that". This is especially true of the calculus, and experience has often shown that, in the case of non-specialist technical students, the calculus is sometimes regarded as a system of purely formal operations. Indeed, Prof. Murnaghan declares in the preface of the book under review: "Many teachers seem to feel, and have no hesitation in expressing their feeling, that it is impossible to teach calculus correctly. The best one can do, they claim, is to give some idea of what the subject is about and to impart, by repeated drill and practice, proficiency in the manipulative details of the subject." It may be remarked here that this refers obviously to the teaching of calculus in America. Is such an experience shared by English teachers? Undoubtedly, many cases could be cited where practical students become fairly expert in manipulative technique without a real understanding of the meaning and necessity for the operations involved. The subject thus becomes purely formal instead of an intelligent aid to calculation.

A brief survey of the history of the concepts of the calculus reveals that many of our great mathematicians left gaps to be filled. As Carl Boyer[2] states: "Although it was Cauchy who gave to the concepts of the calculus their present general form, based upon the limit concept, the last word on rigour had not been said, for it was Karl Weierstrass who constructed a purely formal arithmetic basis for analysis, quite independent of all geometric intuition. . . . In order to secure logical exactitude, Weierstrass wished to establish the calculus (and the theory of functions) upon the concept of number alone." In the great work of Cauchy, two conspicuous failures are noticeable—his omission to define precisely the notion of an infinite aggregate, as well as that of number. Here, it seems, we reach the bedrock of the matter, and it is upon this idea that the present book has been written. To quote again from the author's preface: "We have tried to teach the science of calculation, i.e., of finding the numerical values of functions, without taking the trouble to explain what a number is". The fifteen chapters of the text are thus based upon a lucid discussion in the opening chapter, occupying 48 pages, on numbers, variables and functions. This leads to differentiable functions, the calculation of derivatives, maxima and minima, the theorem of the mean, inverse functions, length of arc, trigonometric functions, antidifferentiation, definite integrals, plane curves, infinite series, tests for convergency and the application of integration. Special emphasis is placed on differentiability rather than on the derivative, and differentiable functions are treated before continuity is considered. Null functions form the basis of the study of limits, and the exponential function is introduced as the inverse of the logarithm.

There is no doubt that "the calculus is the greatest aid to the discovery and appreciation of physical truth; but the basis for this success in all probability is to be found in the fact that the concepts involved were gradually emancipated from the qualitative preconceptions which result from our experiences of variability and multiplicity"[3]. Again, as J. W. N. Sullivan[4] remarks: "A great deal of modern mathematics is the outcome, not of the merely formal development of what was known before, but of a profound critical examination of the foundations of the science".

Prof. Murnaghan's treatment of the subject is thus designed to give the student a deeper understanding of its methods by founding it upon basic concepts. It is therefore a judicious mixture of theory and practice, with the result that many of the explanations have to be very detailed which, in places, renders them somewhat lengthy. On reading through the text, one wonders whether such a treatment will not tend to detract from the interest that should be developed. The whole course is logically sound and marks a commendable break away from the routine methods; but, after all, too great an emphasis upon fundamental concepts is not always an effective introduction to any subject. As many experienced teachers may well ask: Is it not better to defer the consideration of fundamental refinements until a later stage when a student has learned to appreciate some of the difficulties arising from the theoretical basis of the calculus?

Nevertheless, the book may be recommended as a distinct contribution to the subject; but whether it will fulfil its lofty aim, only experience and time will show.

THE PRESENT OUTLOOK IN ARMY EDUCATION

By MAJOR-GENERAL CYRIL LLOYD, C.B., C.B.E., T.D.
Director of Army Education

THE experience gained by Army educationists between 1920 and 1939, the story of Army education during the Second World War and release period, together with the broad principles of post-war development, have been the theme of previous articles (*Nature*, **158**, 775, 821, December 1946). The contrast between the condition of education in the Army after the First World War and after the Second is clearly marked. It is the difference between the newly formed Army Educational Corps struggling against apathy, suspicion and even hostility, and a Corps recognized as an integral part of the national system and a pioneer in the field of further education.

The educational obligation of Service authorities has been defined in the National Service Act of 1947, in which a direct cross-reference to the Education Act of 1944 establishes the full responsibility of the Army to provide further education for all service personnel and to co-operate to the full with all local education authorities to ensure adequate facilities for that education.

The issue of Army Council Instructions authorizing the implementation of a definite plan for Army education which shall supersede that of the release period brings to maturity a scheme which has been in process of preparation for nearly two years. Each stage of the plan has been considered and endorsed by the Army Education Advisory Board under the chairmanship of Sir Philip Morris. The general plan has been designed to meet the educational needs of the peace-time Army and to form an integral part of its training and working programmes. The present transitional stage between the Army Education Scheme for the release period and the greater development towards this post-war scheme is to be known as the interim period.

The object is to provide for the soldier that which is required, educationally, to improve him both as a soldier and as a citizen and to meet his needs as an individual. As part of the national system, its aim is integrated as closely as possible with civilian education, and care has been taken to weld into the scheme provision for both the national service man and the regular soldier. Hitherto the machinery of the Central Advisory Council for Adult Education in H.M. Forces has been instrumental in securing civilian assistance for Army education. Negotiations are now proceeding which will, it is hoped, secure the continuance of this valuable work on a basis suited to the conditions of the peace-time Army on one hand and civil education on the other. Arrangements have also been made with the Ministry of Education for His Majesty's inspectors to co-operate in an advisory capacity with the military inspectors of the Directorate of Army Education, thus placing their experience and knowledge at the disposal of the Army.

The main types of education which will be provided are described as (*a*) general education and (*b*) individual education. The vast majority of the men and women entering the Army are catered for by general education. The soldier must first acquire that fundamental knowledge without which he can be neither an efficient soldier nor a satisfactory citizen. For the first six weeks he will receive instruction for two hours a week in current affairs and citizenship; thereafter time will be increased to three hours weekly, and English, mathematics, history/geography and general science will be added to the curriculum. Courses will be graded in three standards and there will be variations and exemptions for men above average, who will be catered for in ways appropriate to their particular educational needs. At the end of a year's service the national service man will leave the Army; but the regular soldier who remains will continue this work for four hours weekly during a further twenty-four months, after which only current affairs and citizenship will be compulsory, though he may continue his education in working time if he so desires.

The syllabuses are progressive, and these, together with specimen tests of attainment, are to be found in the General Education Handbook. This Handbook was designed for the use of instructors and, used with flexibility and careful selection, it will provide a guide for the establishment of a continuous liberal course of study. The approach in all subjects is adult and is based on the experience and interest of the individual.

General education will be carried out in working time; its counterpart, individual education, will be done in the soldier's off-duty hours in unit classes, educational centres, and Army colleges, under arrangements made with civilian education or by means of the War Office Correspondence Course Scheme. The soldier may undergo courses or pursue activities either to improve his prospects in civil life, or to satisfy his cultural needs or his desire for profitable leisure-time employment. An important aspect of individual education will be the resettlement education of the regular soldier and the development of a resettlement advice service. These activities are additional to continuation studies for those individuals who have reached the standard of School Certificate or other equivalent examination and whose guided reading periods will be catered for by the unit or higher formation reference libraries.

Men of exceptionally low standard will, immediately after enlistment, be given a special full-time course at a preliminary education centre to fit them to join the main stream of general education at a later date. The Royal Army Educational Corps has had considerable experience in combating the problem of illiteracy and as a consequence has evolved practical methods which, combined with sympathetic attention to the personal needs of each individual, have been found to produce a remarkable improvement in the reading age and general attitude of the backward adult.

The scheme will be staffed by full-time Royal Army Educational Corps instructors on an overall scale of one per 240 men, assisted by part-time instructors provided by units. The work of instructors will be supervised by R.A.E.C. officers, of whom, one will be allotted to every 2,400 men. Each supervising officer will act as a travelling headmaster, exercising control over the work of instructors in a group of units. The smoothness of administration and organisation of the Corps is the duty of the R.A.E.C. staff officers provided in the War Office and on headquarter staffs. In the unit it is the commanding officer, with the assistance of his unit education officer, who is responsible for the educational progress of his men, and only through his co-operation can any plan succeed. The regimental officer is responsible for conducting discussions on current affairs and will always be chairman of such discussions.

Many of the present R.A.E.C. instructors are young in experience and, although graduates and trained teachers are to be found within their ranks, it will take time to build up a corps of instructors with a predominance of experienced and academically qualified personnel. The other major difficulty which only time can resolve is that of ensuring continuity of instruction. This will only be fully achieved when the Army as a whole becomes more stable in composition, so that the soldier's service is spent in two or three units at most. Despite these limitations, certain aspects of the plan are already in operation and working well; notably, perhaps, the work with illiterates at preliminary education centres. Here the adult approach through activity is reviving and stimulating interests and skills which have in some cases been dormant for years and in others barely existed. Much valuable work is also being done in the initial stages of the soldier's service, both in the special attention paid to current affairs and citizenship during basic military training, and in the care with which, before being sent overseas, the soldier is briefed as to conditions in the theatre to which he will go and in the historical, geographical and cultural background of the countries concerned. In this latter connexion, a comprehensive series of teaching aids in the form of posters, study briefs, films, film strips, exhibitions, etc., has been prepared and is already in production. In the case of more advanced students, too, there are indications that both unit and centralized library facilities are being used, there is an encouraging demand for correspondence courses, and in many areas civilian resources are being used to the full.

Stated simply, Army education shows to serving men and women how they fit into society as soldiers and citizens, and indicates how individual experience and self-expression may best contribute both to the development of the individual and to the common good. It is not only the future of the Army which is staked upon the training of young service men and women; as the result of their service experience they should return to the civilian community better informed, more self-reliant, in better shape physically, and better equipped both for work and play. In this process it is the task of Army education to give the soldier something which he will recognize as being of permanent value whether he thinks of himself primarily as a worker, as a citizen, or as an individual.

STRUCTURE AND PHYSICAL PROPERTIES OF METALS

THE autumn meeting of the X-ray Analysis Group of the Institute of Physics, held in Birmingham during November 20–21, 1947, was devoted to metals and alloys. The place of X-rays in their study was put in proper perspective: in some of the researches described they provided the main method of attack; in others they were subsidiary.

Dr. W. H. Taylor opened the first session by giving a general account of transformations, referring to the importance of the study of simple alloys as a basis for the study of the more complicated commercial ones. He instanced the order–disorder transformation, and pointed out that X-ray methods permit the study of long-range order, whereas the relationships between near neighbours are physically more significant. The use of crystal-reflected radiation may overcome this disadvantage by allowing changes in background scattering to be observed before ordinary superlattice lines appear[1].

Dissociation has also been studied[2] in the alloy Cu_4FeNi_3. X-ray powder-photographs show 'ghosts' at the sides of the main diffractions, and these are interpreted as evidence of a pseudo-periodic structure due to the incipient dissociation into two phases of similar structure.

A still more detailed investigation has been made of duralumin[3]. Streaks on Laue and oscillation photographs of a single crystal were ascribed to the segregation of copper atoms on sheets parallel to the (100) planes; the break-up of these streaks into spots showed that a metastable structure, $CuAl_2$, was forming, 'keyed' to the main lattice; this structure finally transformed to the stable $CuAl_2$ phase. Thus the changes occurring in age-hardening have been followed in great detail by means of X-rays.

Dr. H. Lipson gave an account of recent work on the alloy $AuCu_3$. Alloys of this type can have a domain structure, and this results in broadening of the superlattice lines with respect to the main lines. Attempts to determine the sizes of the domains from the breadths of the lines, however, yielded inconsistent results[4], and a further condition—for example, that the gold atoms tend to avoid each other[5]—must be imposed. The diffraction effects produced by this condition are unusual; in reciprocal space the superlattice reflexions are represented by disk-shaped volumes of differing orientations[6], and attempts have been made to detect these by means of oscillation photographs of single crystals. MacGillavry and Strijk[7] were unable to find the effect, and claimed that all the spots had cubic symmetry. Edmunds, Hinde, and Lipson[6], with a much smaller crystal, found it, and so did Guinier[8]. Quantitative confirmation, however, is still required, but the investigations promise to provide interesting evidence about transformations on the atomic scale.

Dr. A. J. Bradley presented a different approach to the study of alloys—that of metallography. He emphasized, however, the importance of previous study by X-rays, and gave as an example the system Fe-Ni-Al, in which the results of Köster[9] had been shown to be wrong because the possibility of three-phase regions had not been envisaged[10]. Although slower than the X-ray method, the microscopic method enables the dispositions of the various phases to be studied; Dr. Bradley showed many beautiful examples of photomicrographs of magnification up to 4,000, and claimed to be able to distinguish between ordered and disordered structures. The microscope is of particular value when changes in temperature are to be considered; X-ray methods fail in the Fe-Ni-Al system because high-temperature structures tend to transform on quenching. A high-temperature camera is required, and progress depends upon the production, in the near future, of a suitable instrument.

Mr. H. J. Goldschmidt showed how Dr. Bradley's results had enabled him to interpret some of the X-ray data he had obtained on the permanent-magnet alloys, 'Alnico' and 'Alcomax'. He found 'ghost' lines similar to those given by Cu_4FeNi_3, and said that the pseudo-periodic structure they indicate could be related to some of the microphotographs shown by Dr. Bradley. He also showed how reactions can take place even when the final state is the same as the first, and attributed the changes to Ostwald's law of successive reactions.

In the second session, Dr. G. V. Raynor gave a lecture on the "Electron Theory of Metals". Although this theory is only a part of a much greater whole, in some systems its effects outweigh others; for example, in the copper–zinc system the atoms are so similar in other respects that their difference in valency leads theoretically to results of practical importance.

In metals, the valency electrons are shared by each complete crystal grain—an extreme case of covalent binding. These electrons still have to obey Pauli's exclusion principle that only two (of opposite spin) can occupy the same state; thus the total energy of the valency electrons is quite large, despite the fact that, because of the size of the crystals, the differences in energy between the various states is vanishingly small. The energy is such that the majority of electrons have velocities of the order of 10^9 cm. per sec.

The periodic structure of metals must, however, also be taken into account, and wave mechanics provides a neat method of introducing it. A particle of mass m and velocity v can be considered as a wave-packet of wave-length $\lambda = h/mv$, and if the particle is an electron with velocity 10^9 cm. per sec., λ is about 10^{-8} cm.—the value for X-rays. Thus the electrons can be diffracted by the lattice in which they are moving, and this is the essential feature of the theory.

Suppose we plot, from a fixed origin, radius vectors representing the momenta of the electrons. The momentum defines the electronic state and thus the space—k-space—is, by Pauli's principle, uniformly populated. Owing, however, to the diffraction mentioned above, the distribution of energies between the electronic states shows characteristic variations. It can be shown that those electrons which satisfy the Bragg equation have momenta that lie on planes in k-space, and these planes outline zones known as Brillouin zones; it can further be shown that electrons in states that lie just within the surface of a zone have energies less than the value $\frac{1}{2}mv^2$ for free electrons. Thus structures in which the occupied states reach almost to the surface of the zone will have less electronic energy and consequently a lower total free energy (other things being equal) than those for which the surface is farther away.

Dr. Raynor showed some drawings of Brillouin zones. That for the face-centred cubic structure is far from spherical; thus the addition of zinc to copper allows the electrons to reach the surface, and the advantage of the depressed energy is utilized; but with further addition of zinc, the energy increases rapidly because the electrons have to be accommodated in the more remote corners. The rapid increase sets in at about 1·4 electrons per atom, in agreement with the solubility of zinc in copper. The body-centred cubic structure is more nearly spherical, and the γ-structure still more nearly so; this, then, explains the sequence and compositions of phases in the Cu-Zn system. In the hexagonal structures that occur in zinc-rich alloys, the nature of the overlap into the second zone is of importance, and Dr. Raynor showed how the variation of axial ratio in these phase fields can be accounted for on the electron theory.

Dr. Raynor concluded by giving an account of the experimental work he is pursuing in order to test further predictions of the theory and to investigate the modifications introduced by other factors.

The final session was devoted to matters of more industrial interest. Dr. T. Ll. Richards described the application of X-ray methods to the study and control of preferred orientation and consequent anisotropy in non-ferrous alloys. The deleterious effect of such anisotropy in annealed copper strip was well illustrated by a pressing in the form of a cup made from the strip; this should have had a flat top, but instead had four pronounced 'ears'. Anisotropy in cold-rolled strip, however, is not necessarily due to preferred orientation; it can be due to structural defects on the planes of maximum resolved shear, inclined at 45° to the rolling direction. This effect was illustrated in a photograph of a strip of considerably over-rolled aluminium alloy.

A preferred orientation of crystals is developed by both hot- and cold-working. In the cold rolling of face-centred cubic metals, for example, the crystal grains tend to orient themselves so that a given plane, for example, (110), is parallel to the plane of rolling, and a given direction in that plane, for example, [112], is in the direction of rolling. Many such combinations are possible[11], but the twin (110) [112] textures are predominant in heavily cold-rolled copper strip. Depending on the magnitudes of the initial grain size, cold-rolling reduction, and the final annealing temperature, the twin textures merge together on annealing[12] to form the single (100) [001] texture, so that the resulting material has almost the anisotropy of a single crystal, with the resultant unwelcome directional properties. A clear understanding of the influence of these factors is necessary for the production of directionality-free strip.

Dr. A. Hargreaves described a corresponding research on rolled magnesium alloy. Since magnesium is hexagonal and thus has one unique direction in each crystal grain, the number of possible modes of reorientation after working is less than in cubic crystals. In practice, it is found that this unique direction [001] is approximately perpendicular to the plane of the sheet, and that the variation (of about 25°) is mainly along the direction of rolling. If, however, the direction of the [001] axis is examined at different depths in the sheet, by means of surface-reflexion photographs from successively etched surfaces, it is found not to be random; it starts at 0° in the surface and increases within the body of the sheet to 15°. This is so for both surfaces, and thus in the body of the sheet there is a mixed orientation of (0001) planes making angles of about 30° with each other[13]. Dr. Hargreaves showed that transmission photographs with a hard radiation would give only an average of these results; the detailed variation with depth would be missed.

Dr. Hargreaves described a moving-film method with which metallic textures could be determined, and pointed out the advantages of obtaining on a single film the information normally obtained only from a series.

Mr. N. F. Astbury read a paper, prepared in conjunction with Dr. Scholefield and Mr. De Barr, on the iron–silicon alloys used for transformer sheets. These alloys, which contain about 4 per cent silicon, have the body-centred cubic structure of α-iron. It is known that magnetic saturation of a single crystal of iron is produced with lowest field-strength if this field is applied in the [100] direction, and thus, if the alloy can be prepared with the [100] direction in the direction of rolling, the magnetic performance in this direction will be superior to that obtained with randomly oriented material. Thus preferred orientation is sought for, not avoided.

Mr. Astbury described the treatment that has been found to work in practice. He emphasized, however, that other considerations are important; traces of carbon or sulphur can more than cancel out the gains made by the processing.

Several methods are in use for examining the texture; X-ray methods are not necessarily the most useful, since the large grain-size introduces difficulties in obtaining ordinary polycrystalline photographs, and in some cases other methods such as measurement of magnetic or strain anisotropy, or optical reflexion from etch pits, are more informative. X-rays still provide a basis for interpretation of the other results.

Each session of the conference was followed by discussion in which many of the points made by the speakers were enlarged upon. These discussions brought out very well the importance that metallurgists attach to X-ray methods and the interest the X-ray crystallographers have in the metallic state.

GEOLOGY OF THE SALT RANGE OF THE PUNJAB

IN the issue of *Nature* of March 23, 1946, p. 359, I gave a résumé of a "Symposium on the Age of the Saline Series of the Punjab", held at Poona in 1944 under the auspices of the National Academy of Sciences of India (published 1945[1]). At the time I wrote, a second symposium had already been held on the same subject at Udaipur in 1945 (published 1947[2]). Page references in the sequel refer to this second symposium.

The point at issue, it will be remembered, is whether the Punjab Saline Series, which commonly occurs beneath fossiliferous Cambrian at the foot of the Salt Range escarpment, is of Cambrian or Tertiary date. The interval between the appearance of the reports of the two symposia has been well employed by the main protagonists, E. R. Gee and B. Sahni. Gee has led two additional excursions to exposures which he considers leave no doubt of the 'natural' superposition on the Saline Series of, in some places, Cambrian Purple Sandstone, and, in others, unconformable Carboniferous Talchir Boulder Bed. His companions have been, at one locality or another, J. B. Auden, J. Coates, B. S. Downward, W. D. Gill, B. S. Lamba, G. M. Lees, E. S. Pinfold, B. Sahni and M. R. Sahni (pp. iv, 95; Gee, Coates, Lamba, Pinfold and B. Sahni have published in the second symposium, though Coates only in the general discussion, p. 240). Sahni, as well as accompanying Gee on the two excursions, has had much to do with mobilizing further palæontological evidence, now published by himself, M. S. Mani, J. Hsü, R. N. Lakhanpal, B. S. Trivedi and R. V. Sitholey (see list of contributors). Furthermore, Sahni has taken advantage of a visit to Britain to give a number of demonstrations (p. xxxix). I shall always treasure the memory of how perfectly Sahni and Pinfold, out-and-out opponents, co-operated on one of these occasions at the British Museum (Natural History) to make certain that those who attended should understand all sides of the question.

Eleven other authors, not mentioned above, have sent in contributions to the second symposium, though for the most part they had not undertaken recent special investigations; and two more, similarly situated, are recorded among those who joined in the general discussion. In what follows I make no detailed attempt to attribute particular ideas to particular authors; but for brevity treat Sahni as representing the Tertiary correlation, and Gee the Cambrian. I also assume that readers can turn back to my previous digest. I confess that I have not reached a firm conclusion; but I do incline to the view that Sahni is correct. I say this in the full knowledge that most of my brother field-geologists will disagree with me.

Let it be granted that so many specimens of the Saline Series have been sampled that we know there is throughout its components (salt, saline marl, dolomite, oil-shale) a quasi-universal distribution of organic debris in the form of almost microscopic dust.

This proposition, advanced by Sahni, does not seem to have been challenged by anyone. It has been argued that the dust may have been introduced into the host-rocks long after the formation of the latter, and may have no more significance for dating these rocks than water or oil commonly found in sandstones. I confess that we have here a conception, so wonderful, regarding subterranean travel of dust, that I shall feel more than compensated for my incredulity if such migration be eventually proved. My incredulity is for the present strengthened by learning that Gee seems as unwilling as myself to invoke migration to account for the contents of certain oil-shales that he accepts as an integral part of the Saline Series (p. 96). "It is agreed," he says, "that the kerogen and free oil is indigenous in the shales, and that it has been derived from either vegetable or animal remains." But he adds: "No evidence of animal remains within the oil-shales has been met with, though many geologists have made an intensive research. What is the evidence of the plant remains that have so far been recognized in these oil shale strata; can they not possibly represent a Cambrian flora?" Sahni's reply is: "Mr. Gee's statement that 'no evidence of animal remains within the oil shales has been met with' evidently refers only to macrofossils. The microfossils described and figured by Messrs. Trivedi, Mani and Lakhanpal and by myself are on the table, open to inspection, along with the rocks from which they were prepared" (p. 246). Another, though less potent, argument against the subterranean dust-diffusion hypothesis is that, in three localities tested in detail, "while angiosperm and insect remains always occur in the Saline Series rocks (that is, below the suspected thrust-plane) there is no trace of these groups in any of the samples taken from the overlying Palæozoic beds, respectively the Purple Sandstone, the Lower Gondwana shales within the Productus Limestone, and the Talchir shales in the Talchir Boulder Bed" (p. 245; also pp. xviii, xl, 92). Of course, Gee, Sahni and everyone else recognize that the saliferous members of the Saline Series are peculiarly liable to subterranean contamination from without. The only difference of opinion is as to the possibility or impossibility of quasi-universal contamination by introduced dust.

Let it be granted that the dust found everywhere in the Saline Series includes so many examples of recognizable debris of conifers, angiosperms and insects as to be on the whole clearly post-Cambrian. This second proposition I am prepared to take as a working hypothesis from Sahni and his co-workers. I admit that it involves two separate debatable sub-propositions:

(1) Sahni and his co-workers are certain that the dust particles, which they recognize as remains of conifers, angiosperms and insects, are unmistakable. They publish numerous illustrations, some of them photographs. If botanists and zoologists are withholding criticism out of regard for the authors, they are doing a disservice to science. Gee has asked whether the chitinous dust might not have come from trilobites, rather than insects, and has received an apparently satisfactory answer (pp. 233, 235).

(2) Sahni and co-workers are certain that the particular dust particles, which they identify as bits of conifers, angiosperms and insects, have the same wide distribution as the organic dust as a whole. It might otherwise be suggested that such identifiable material is probably in small proportion and reasonably assignable to contamination. This idea seems to be implicit in Gee's question as to whether the organic remains in the oil-shales might not present a special problem (p. 96), and prove free from post-Cambrian types; but the answer given by Sahni and co-workers is clear, for they maintain that remains of conifers, angiosperms and insects do occur in the oil-shales (pp. ix, xvii, xxii, 53, 187, 204, 205, 207, 220).

Let it be granted that Gee has demonstrated, on three occasions to first-class audiences in the field, exposures which seem to prove that the Saline Series is 'naturally' overlain by unquestionably Palæozoic formations.

Five of Gee's companions have openly adopted his interpretation. Only Sahni himself has said in print that he has seen and disbelieved. The evidence derives in part from lack of manifest disturbance at the contact, and in part from contained fragments in the base of the Talchir Boulder Bed, where this latter happens to be the lowest member of the overlying succession.

Above are stated the three assumptions which for the time being guide my conclusions. I think Sahni is right in interpreting the organic dust in the Saline Series as wind-borne, and contemporaneous. Accordingly I think that the apparent sub-Cambrian stratigraphical position of the Saline Series is misleading. I realize how seldom a major thrust can escape detection in a non-metamorphic, well-exposed succession; but I do know one case in Scotland, that of the Kishorn Thrust, a mile south of Broadford, where Torridon Sandstone is brought on to Durness Limestone in such a manner that any one of us might be deceived if he did not know the answer in advance. Let us hope that further research will soon put the Salt Range problem beyond dispute, one way or the other.

Since this review was written, I have read an extremely important letter by A. K. Ghosh and A. Bose (*Nature*, December 6, 1947, p. 796), in which the discovery is announced of plant dust of apparent post-Palæozoic type in the Salt Pseudomorph Beds. These beds intervene between the Talchir Boulder Bed, above, and the fossiliferous Cambrian, below, instead of underlying the latter as does the Saline Series so far discussed. The elaboration of this find may well lead to decisive results. At first sight it seems rather to weaken Sahni's position.

In conclusion, it is right to express admiration for the organisation displayed by the National Academy of Sciences of India. Perhaps one suggestion may be proffered. Readers would greatly appreciate guidance from page headings.

E. B. BAILEY

SIR CHARLES SHERRINGTON AND DIPHTHERIA ANTITOXIN

AT a recent informal gathering of some men of science an important matter of scientific interest was brought up by Dr. A. N. Drury, director of the Lister Institute, recording an incident in which Sir Charles Sherrington had played a part more than half a century ago.

The incident concerned the very first occasion on which diphtheria antitoxin was made in England. Dr. Drury exhibited one of the hooves, suitably mounted, of "Tommy", the first horse to be injected in England with diphtheria toxin with the object of obtaining diphtheria antitoxin for clinical use; and he explained how the Brown Institution came to be associated with the British Institute of Preventive Medicine—as the Lister Institute was then called—which had accommodation for small animals only in the kitchen of the private residence in which it was housed. Dr. Drury described how "Tommy" was stabled at the Brown Institution, and how that, here, Dr. Armand Ruffer, then secretary of the British (now Lister) Institute, and Sir Charles Sherrington, who was at that time professor-superintendent of the Brown Institution, made those first injections and withdrew those samples of blood which yielded the first British-made diphtheria antitoxin. Listeners were also interested to learn that "Tommy's" performance as an antitoxin-producer would rank high even at the present day. Many other attendant circumstances of the incident and the time (August 1894 and the later months of that year) were reported by Dr. Drury, among which may be mentioned the lively interest of Sir Joseph Lister (as he then was); the sending of diphtheria antitoxin from Paris to be tried on patients in England pending the material from the horse "Tommy" and, no doubt, other horses immunized by Dr. Ruffer and Sir Charles Sherrington, becoming available; Pasteur's interest and concern that those attempting its preparation in England should benefit by the experience of those colleagues in France who had succeeded in preparing this entirely new type of medicament; and the clinical experience of English medical men who were privileged to use these early preparations. A letter from Dr. Roux of the Pasteur Institute, and others from practitioners who used the antitoxin, were read and exhibited.

Dr. Drury's clear exposition of this historic event, and the unique character of the exhibits connected with it, aroused the greatest interest, and it was agreed that Sir Charles Sherrington's interest would be even greater. A letter was accordingly written and the following is an extract from his reply dated November 15, 1947:

". . . Thank you for kindly writing. Yes, the story was just as you say; except that dear Ruffer's first name was *Armand*. Poor fellow, he was torpedoed and drowned by the Germans in the 1st world war. He was brother-in-law to Bouchard of Paris, the leading French physician in his line.

"The story of the horse at 'the Brown' had a dramatic sequel which perhaps Dr. Drury has not heard; if he has, he will, I hope, forgive my telling it; it may interest you. Ruffer and I had been injecting the horse—our *first* horse—only a short time. We were badly in the dark as to the dosage to employ, and how quickly to repeat the increasing injections. We had from it a serum partly effective in guinea pigs. Then, on a Saturday evening, about 7 o'clock, came a bolt from the blue. A wire from my brother-in-law in Sussex. 'George has diphtheria. Can you come?' George, a boy of 7, was the only child. The house, an old Georgian house, 3 miles out of Lewes, set back in a combe under a chalk down. There was no train that night. I did not at first give thought to the horse, and, when I did, regretfully supposed it could not yet be ripe for use. However, I took a cab to find Ruffer. No telephone or taxi in those days—'93 or '94. Ruffer was dining out. I pursued him and got a word with him. He said 'By all means you can use the horse, but it is not yet ripe for trial'. Then by lantern-light at 'The Brown' I bled the horse into a 2-litre flask duly sterilized and plugged with sterile wool. I left the blood in ice for it to settle. After sterilizing smaller flasks, and pipettes and some needle-syringes I drove home, to return at midnight, and decant the serum, etc.

"By the Sunday morning train I reached Lewes. Dr. Fawssett of Lewes—he had a brother on the staff at Guy's—was waiting in a dog-cart at the station. I joined him carrying my awkward package of flasks, etc. He said nothing as I packed them in, but, when I had climbed up beside him, he looked down and said, 'You can do what you like with the boy. He will not be alive at tea time.' We drove out to the old house; a bright frosty morning. Tragedy was over the place, the servants scared and silent. The boy was very weak; breathing with difficulty; he did not seem to know me. Fawssett and I injected the serum. The syringes were small and we emptied them time and again. The Doctor left. I sat with the boy. Early in the afternoon the boy seemed to me clearly better. At 3 o'clock I sent a messenger to the Doctor to say so. Thence forward progress was uninterrupted. On Tuesday I returned to London, and sought out Ruffer. His reaction was that we must tell Lister about it. The great surgeon (not Lord Lister then) had visitors, some Continental surgeons, to dinner. 'You must tell my guests about it', he said, and insisted—so we told them in the drawing-room, at Park Crescent. The boy had a severe paralysis for a time. He grew to be 6 ft. and had a commission in the 1st world war.

"If Drury has not heard of this sequel to the first horse at 'the Brown' he may like to hear it; please give him my best remembrances. . . . Thank you so much for writing. . . ."

OBITUARIES

Prof. A. N. Whitehead, O.M., F.R.S.

ALFRED North Whitehead was born on February 15, 1861, the son of the Rev. Alfred Whitehead, at that time the headmaster of a private school in Ramsgate, and later vicar of St. Peter's, Isle of Thanet, and honorary canon of Canterbury. From Sherborne School he proceeded in 1880 to Trinity College, Cambridge, of which foundation he became a fellow in 1884 and lecturer in 1885.

As a young man, he had a place apart among Cambridge dons by reason of his interest in the outlying and comparatively unknown branches of mathematics. In the nineteenth century, this category included non-Euclidean geometry and non-commutative algebras, such as matrices and symbolic logics; and on these subjects he published in 1898 a massive and very original volume, under the title "A Treatise on Universal Algebra, with Applications".

It is interesting to observe how Whitehead's prophetic instinct led him to take up subjects which were at the time neglected and unknown to most professional mathematicians, but which have since played a great part in the interpretation of Nature. Matrix theory first came into its kingdom in 1925, when Heisenberg, Born and Jordan showed that by its aid quantum theory could be constituted as a complete logical structure. The non-Euclidean geometry of spaces of constant curvature has found its chief application in the cosmological investigations of Eddington and others from 1930 onwards, though Euclidean space had been dethroned fifteen years earlier by Einstein's theory of general relativity. The "Universal Algebra" was acclaimed on all sides as a splendid work of learning and research, and the reputation based on it led to Whitehead's election as a fellow of the Royal Society in 1903.

Of the scholars of Trinity who sat at Whitehead's feet during the last decade of the nineteenth century, there was one who became a specially attached disciple and played a great part in his subsequent life and work. This was Bertrand Russell, who entered the College in 1890 and was elected a fellow in 1895. In 1900 he and Whitehead attended an International Philosophical Congress in Paris, at which they heard an account of the work of Giuseppe Peano, who in the years immediately preceding had invented a new ideography for use in symbolic logic. They realized that Peano's symbolism was vastly superior to anything that had been known previously, and resolved to devote themselves to its development, and in particular to try to settle by its means the vexed question of the foundations of mathematics.

The thesis which they now set out to prove was that *mathematics is a part of logic*; it is, as they said, the science concerned with the logical deduction of consequences from the general premises of all reasoning; so that a separate 'philosophy of mathematics' simply does not exist. This, of course, contradicts the Kantian doctrine that mathematical proofs depend on *a priori* forms of intuition. They soon succeeded in proving that the cardinal numbers 1, 2, 3, . . . can be defined in terms of concepts which belong to pure logic, and which can be represented by Peano ideograms. From this first success they advanced to the investigations published in the three colossal volumes of "Principia Mathematica", which appeared during 1910–12 and contain altogether just under 2,000 pages.

In 1910 Whitehead resigned the Trinity lectureship and removed to London. During 1911–14 he was on the staff of University College, and from 1914 until 1924 he held a chair of mathematics in the Imperial College of Science and Technology.

There was to have been a fourth volume of the "Principia", dealing with geometry. But as Whitehead worked in preparation for it, he found himself more and more involved in questions which really belonged to epistemology and metaphysics. During 1915–17 he published several papers of a definitely philosophical character, and these were followed by two books in which he propounded a new philosophy of the external world, "An Enquiry concerning the Principles of Natural Knowledge" in 1919, and a volume of Tarner Lectures on "The Concept of Nature" in 1920. He first cleared the ground by rejecting the conceptions of Nature which then formed the accepted starting-point of physics: namely, that space and time provide, so to speak, a stage, on which ponderable bodies, æther, and electricity maintain an unending performance. In place of this, he put forward the doctrine that the ultimate components of reality are *events*. For example, a university lecture is an event: obviously it includes other events, such as the professor at his rostrum and the students at their desks; moreover, it may in its turn be regarded as a part of a larger event, such as the aggregate of all the lectures given in the same building at the same hour. This property of *extending over* other events is characteristic of events, and is the fundamental relation on which Whitehead's philosophy of the external world is based.

An event is never instantaneous; it always endures over a certain (though perhaps very short) duration of time: "the ultimate fact for observational knowledge", as he said, "is perception through a duration". The notions of an *instant* of time and a *point* of space are not truly primitive notions: to obtain them, he introduced what he called the *method of extensive abstraction*. The idea of this method is to consider a set of events each of which includes all the subsequent members of the sequence, like a nest of boxes each slightly larger than the one next inside it; if the events ultimately diminish indefinitely (or in more precise language, if no event is extended over by every event of the set) then they may be regarded as defining a limit: points of space and instants of time may be defined in this way; so that time and space are derivative concepts, they are abstractions which express relations between events.

In 1924 Whitehead resigned his chair at the Imperial College in order to accept a professorship in the Philosophical Department of Harvard University, which he occupied until his final retirement in 1937. In the session 1927–28 he returned to Britain for a time in order to deliver the Gifford Lectures in the University of Edinburgh. These, which were published in 1929 under the title "Process and Reality: an Essay in Cosmology", may be regarded as the definitive exposition of his mature philosophy, to which he gave the name 'Philosophy of Organism'. In his own words, "Speculative Philosophy is the endeavour to form a coherent, logical, necessary system of general ideas in terms of which every element of our experience can be interpreted". His point of view in this endeavour must first be made clear. He turned his back on German idealist philosophy (Kant, Fichte, Schelling, Hegel), which was concerned chiefly with mind, and had little interest in the study of Nature by the methods of mathematical and experimental science. In this sense his philosophy is, as he said, "a recurrence to pre-Kantian methods of thought". In regard to particular features, he was under obligations of one sort or another to Descartes, Leibnitz, Locke, Berkeley and Hume, and among moderns to Bradley, Bergson and Alexander; but the main roots of his doctrine were to be found in Greek philosophy, and it bore a relation to modern science which may be compared with that which Platonism bore to the Pythagorean mathematical concept of the intelligible element in Nature.

The philosophy of Whitehead is in the first place a cosmology. Now one famous philosophical cosmology has come down to us from the ancient world, namely, that set forth in the "Timæus" of Plato; and the resemblances between it and Whitehead are so striking that "Process and Reality" may be described, in a first rough approximation, as the "Timæus" brought up to date. The fundamental idea in both is the gradual evolution of order out of a primeval chaos, by a process of divine achievement. The *demiourgos* of the "Timæus" corresponds to Whitehead's God, and the Platonic 'Ideas' or 'Forms' correspond to Whitehead's 'eternal objects', which have a potentiality of 'ingression' into the becoming of actual entities, just as the 'Forms' have participation (*methexis*) in visible things. The primitive plastic substratum in which copies of the 'Forms' are made (*chora*) corresponds to Whitehead's concept of 'creativity'.

"Process and Reality" is not an easy book to read, chiefly because of the multitude of new words, and new senses of old words, with which it teems. Only time can show how many of these will be retained as a permanent enrichment of the philosophical vocabulary.

Whitehead died at Cambridge, Mass., on December 30, 1947.

EDMUND T. WHITTAKER

ON November 12, 1947, it came my way to spend, alone, a couple of hours in the evening with the late Prof. Whitehead, and Mrs. Whitehead, in their apartment within a stone's throw of the centre of Harvard. It seems likely, therefore, that I was the last person from Britain to see the great man before he died.

We talked of Trinity ("Such a good place", he whispered) and its 'characters', of whom he spoke affectionately, coupled with an occasional sly dig, as entrancing as it was kindly. He was devoted to the country of his adoption: a remark stands out in my memory—"The Americans have a streak of tenderness, yes, how valuable that is these days". Many people have used gracious words about our trans-Atlantic cousins, but it was left to him to state, quite simply and naturally, their noblest trait, and the one holding out hope for the world.

In appearance, Whitehead had become almost 'other-worldly' (something which others besides myself had noticed), as if, for him, the veil was wearing very thin. Yet there he sat, erect in his big arm-chair, full of life and interest in other people. I thought he might be getting tired, and rose to go. He, rather slowly, grasped my hand and held it, saying "Come again". But that was not to be.

F. IAN G. RAWLINS

Prof. J. N. Brønsted

PROF. JOHANNES NICOLAUS BRØNSTED died in Copenhagen on December 17, 1947, after holding the University chair of physical chemistry for nearly forty years. He was born in 1879 and spent his childhood in Jutland, where his father was employed as an engineer in connexion with land reclamation. Both his parents died while he was still a boy, and after going to school in Aarhus and Copenhagen, he began training as an engineer at the Polytechnic Institute in Copenhagen in 1898. However, it soon became clear that his interests were in chemistry, and he took the *Magister* degree in this subject in 1902, being appointed as assistant at the University Chemical Laboratory in 1905. He very soon became engrossed in the application of thermodynamics to physico-chemical problems, a subject which was to prove a central theme in all his subsequent work. A long series of papers in the years 1906–21 dealt with the theory and measurement of affinity changes, and it was the third of this series (dealing with binary mixtures) which was presented for his doctorate degree in 1908. In 1909 he was appointed (after close competition with Niels Bjerrum) to the newly instituted chair of physical chemistry, and was also made director of the physical chemistry laboratory of the Polytechnic Institute, where a great deal of his later work was carried out.

Some of Brønsted's work on affinity had dealt with electrolyte solutions, and in the period 1918–24 these became a special focus of interest. In particular he carried out an extensive series of solubility measurements, and was able to establish several simple and important general laws. When the theory of Debye and Hückel was published in 1923, it was satisfactory to find that its predictions agreed essentially with the relations already established by Brønsted, and the solubility measurements of Brønsted and LaMer (1924) still constitute some of the best evidence for the Debye–Hückel theory.

At about the same time Brønsted became interested in the kinetics of reactions in electrolyte solutions, and our present understanding of kinetic salt effects rests largely on his papers of 1920–24, which clarified a confused subject in a remarkable manner. This work directed his attention to acids and bases, and it is in this connexion that his name is most widely known to-day. The modern definition of acids and bases (proposed simultaneously in 1923 by Brønsted and by T. M. Lowry) has had a great clarifying influence in many branches of chemistry. In particular, it led to the idea of general acid-base catalysis, and although this idea had been previously suggested by H. M. Dawson and others, it was most clearly presented and justified in a series of papers by Brønsted and his colleagues on the decomposition of nitramide, the mutarotation of glucose, and various hydrolytic reactions.

In 1930 Brønsted moved to the new Physico-chemical Institute, where he enjoyed much better experimental facilities and a charming official residence. Here he continued work on reaction kinetics, especially in non-aqueous solvents, but also returned to thermodynamic problems. These latter included studies of the effect of molecular size on the thermodynamic properties of hydrocarbons, polymers and colloids. He also published several papers on the fundamental basis and formulation of the laws of thermodynamics, a subject which occupied his attention increasingly right up to his death.

Brønsted's fame to-day probably rests largely on his work on reaction kinetics and his definition of acids and bases, and it is perhaps not always realized how much he contributed to the fundamental thermodynamics of solutions. This firm foundation in thermodynamics left its mark on all his work, where an exact and elegant formulation of experimental conclusions was often coupled with a reluctance to speculate in terms of molecular models. Although he contributed little to the elaboration of practical techniques, his experimental work showed great skill in the choice of methods and of systems for investigation. He preferred to work independently of others, and the only notable example of collaboration outside his own field is his well-known work with G. von Hevesy on the separation of the isotopes of mercury. He did not suffer fools gladly among his research students; but it was a great inspiration to work under his guidance, and many foreign visitors enjoyed the hospitality of his laboratory from 1920 onwards. Brønsted himself travelled widely in Europe and paid one visit to the United States as a visiting professor at Yale. He received many honours from learned bodies abroad, such as the American Academy of Arts and Sciences, the Chemical Society of London, and also from the University of London.

Brønsted was a man of great personal charm and took a keen interest in the art, literature and natural history of several countries besides his own. During most of his life he played little part in public affairs, but the German occupation of Denmark led him to think more deeply on national and international questions, and in 1947 he became a member of parliament, though his last illness prevented him from taking his seat. He was one of the small band of great men of science who have given Denmark a scientific reputation quite out of proportion to her size, and he will be mourned by friends and colleagues in many parts of the world. R. P. BELL

Mr. Orville Wright

THE death on January 30 of Orville Wright marks the passing of the second of the great co-pioneers of mechanical flight (Wilbur Wright died in 1912), and of the man who actually made the first controlled and sustained flight in an aeroplane. Orville was born at Dayton, Ohio, on August 19, 1871, and was the fourth son of Bishop Milton Wright, Wilbur being the third. The two brothers grew up inseparable in youth and manhood; so close was their collaboration that their experimental work can be regarded only as a single achievement—though Wilbur, on account of his age and special gifts, may have been the leader.

In contrast to some other investigators, the Wright brothers approached the problem of flight by the method known to have been employed in Nature many millions of years ago, namely, through the evolutionary process of gliding, which they saw to be obligatory. Their contribution was, essentially, the devising of a complete system of control where none had previously existed; the design of effective cambered wings, determined by wind-tunnel research; the development of airscrews and the adaptation of a petrol engine; and, finally, the incorporation of all these devices in a practical machine.

The unique distinction of being the first man to fly in the true sense—which fell to Orville at Kitty Hawk, North Carolina, on December 17, 1903—was borne by him with dignity and charm. After the untimely death of his brother Wilbur, he took a less active part in aeronautics, though his interest never waned. More recently, he was concerned with establishing the credit properly due to them for their historic achievement, and in 1928 he sent the original biplane of 1903 to the Science Museum in London in order to receive that unqualified recognition which he feared was not forthcoming in some quarters of his own country. The machine is still on exhibition there.

M. J. B. Davy

We regret to announce the following deaths:

Dr. Bernard Dyer, well-known agricultural chemist and public analyst, formerly president of the Society of Public Analysts and Other Analytical Chemists, on February 12, aged ninety-one.

Prof. R. B. Thomson, emeritus professor of botany, University of Toronto, well known for his work on plant anatomy and morphology, on July 31, 1947, aged seventy-six.

NEWS and VIEWS

Dr. S. E. Sheppard

Dr. S. E. Sheppard, well known throughout the photographic industry, retired on January 1, 1948, after thirty-five years with the Eastman Kodak Research Laboratories, Rochester, U.S.A. Dr. Sheppard graduated at University College, London, where he later obtained the degree of doctor of science, submitting a thesis on the formation of the latent photographic image and the chemistry of development. The work was done jointly with Dr. C. E. K. Mees, now a vice-president of the Eastman Kodak Company, and was published as "Investigations on the Theory of the Photographic Process", so well known by photographic research workers. In 1913 the Eastman Kodak Research Laboratories were newly organised and Dr. Sheppard went to the United States to join the staff as a chemist, and since then he has made valuable contributions in many fields of photographic research. Perhaps his best-known work relates to the function of gelatin in photographic emulsions. He and his co-workers found that the sensitizing action of gelatin is influenced by the presence of certain sulphur compounds, among the most important of which are derivatives of mustard oil. This work has led to the comment among those familiar with photography that if the cow had not a taste for mustard we should have no fast photographic emulsions. Dr. Sheppard made a special study of colloid chemistry which, apart from its obvious influence on his work on gelatin, led to such unrelated work as the development of a colloidal fuel for use in submarines during the First World War and investigations into the properties of cellulose and rubber. He has published some two hundred and fifty scientific papers and written several books; the value of his contributions to photographic science has been recognized by honours conferred upon him by photographic and chemical societies on both sides of the Atlantic.

Harrison Memorial Prize: Dr. D. H. R. Barton

The Harrison Memorial Prize for 1947 has been awarded to Dr. D. H. R. Barton. Dr. Barton studied at the Imperial College of Science and Technology, London, where he graduated in 1940 with first-class honours, being awarded the Hofmann Prize for special distinction in organic chemistry; he is now an I.C.I. Research Fellow in the Department of Inorganic and Physical Chemistry at the Imperial College. The Harrison Memorial Prize is awarded by a committee, consisting of the presidents of the Chemical Society, the Royal Institute of Chemistry, the Society of Chemical Industry and the Pharmaceutical Society, to a British chemist less than thirty years of age for original chemical investigations during the previous five years.

British Museum (Natural History)

The Principal Trustees of the British Museum have appointed Mr. David Dilwyn John and Dr. Francis Charles Fraser to be deputy keepers in the Department of Zoology of the British Museum (Natural History). Mr. John, who is forty-six, has been in charge of Recent echinoderms at the Museum since he joined the staff in 1935. He studied zoology in the University of Wales and served during 1925–35 on the scientific staff of the "Discovery" Investigations, during which period he took part in three commissions in Antarctic waters. On the third of them, while he was scientific officer in charge, the Antarctic continent was circumnavigated, chiefly in the winter months. He has been awarded the Polar Medal. During the War he served in the Royal Artillery. Dr. Fraser is forty-four years of age, and served with "Discovery" Investigations during 1925–33, and has received the Polar Medal for three periods of service in the Antarctic. He joined the Museum staff in 1933, since when he has been in charge of the osteological collections, and has made a special study of whales.

British Institute of Archæology in Ankara

The British Institute of Archæology in Ankara was formally inaugurated on January 15 by H.E. Resat Semsettin Sirer, Turkish Minister of National Education and H.E. the British Ambassador, Sir David Kelly, in temporary quarters at 8 Istiklâl Caddesi, Ankara. Members of the Turkish Council of Ministers and the Diplomatic Corps were present, and were received by Prof. John Garstang, director of the Institute, and Mrs. Garstang. The Institute is a newly founded body, designed to carry out work similar to that of the other British Schools of Archæology at Athens, Rome, Jerusalem and Baghdad. It will form a centre of research to which British students of archæology and kindred subjects such as anthropology and ethnology will go to carry out their work. For this purpose the Institute is bringing together a library and collections of archæological objects, photographs and squeezes of inscriptions in so far as these are necessary to supplement the collections in Turkish museums. It is offering this year a scholarship of £300 to a student wishing to carry out researches in Turkey in some aspect of Anatolian archæology. It is also hoped to offer such a scholarship annually and a fellowship of £350 to an advanced student.

As a contribution to research in the archæology of Turkey and as a valuable means of training students, the Institute will undertake, as soon as funds are forthcoming, a programme of excavation of sites in Turkey and of archæological exploration on the surface. It will also give all assistance possible to approved British expeditions for excavation or other research. For the information of would-be students, the following rough estimate of expenses may be useful: living in Turkey, average £T5 per day for 100 days (say, £50); travelling from Britain and back £120; incidental expenses during stay £30; balance for travel and expenses of research in Turkey £100 (total £300). The Institute is organised under a committee in London, on which there are representatives of the British Academy, the British Museum, the London Institute of Archæology, the British School at Athens, the Society for Hellenic Studies, the School of Oriental Studies, the Royal Society, the Society of Antiquaries, the Royal Asiatic Society, the Royal Anthropological Institute, as well as official representatives of the Universities of Oxford, Cambridge, London and Edinburgh. The committee's honorary secretary in London is Miss K. Kenyon, c/o Institute of Archæology, Inner Circle, Regent's Park, London, N.W.1.

Transit Circle for the Royal Observatory, Greenwich

WHEN the Royal Observatory moves from Greenwich to Herstmonceux, the Airy transit circle, which was installed in 1851 and which marks the zero meridian of longitude, will be left at Greenwich, along with a collection of older instruments dating back to the time of Halley. They will form an interesting historical exhibit. The Airy instrument has reached the end of its useful life; the objective has twice been repolished and refigured and is too thin for a further repolishing which is now needed; many of the circle graduations have been almost obliterated by repeated cleaning; the instrument is non-reversible and obsolete in various respects. The Observatory possesses a modern reversible 7-in. transit circle, made by Cooke, Troughton and Simms, and installed in 1936, which is required primarily for fundamental observations. A second transit circle is needed for differential zone observations.

When the Astronomer Royal, Sir Harold Spencer Jones, was in Australia last year, he visited the Melbourne Observatory, which was recently closed. Much of its work has been taken over by the Commonwealth Observatory at Mount Stromlo near Canberra. There he saw an 8-in. reversible transit circle, of 12-ft. focal length, with two circles of 3-ft. diameter. It was made by Troughton and Simms, and installed in 1884; an impersonal micrometer has since been provided for it. The instrument had been used with care and was in excellent condition. When the Government of Victoria was made aware of the requirement for such an instrument by the Royal Observatory, it generously decided to present the telescope. The instrument was dismantled and packed with the assistance of the Royal Australian Navy, and has recently arrived at Greenwich. It will be installed at Herstmonceux in due course.

The Biometric Society: British Region

THE Biometric Society, a new international organisation the aim of which is the furtherance of quantitative biology in all its aspects, came into being at a conference held in Woods Hole, Massachusetts, during September 1947. Its president is Prof. R. A. Fisher, and its secretary, Dr. C. I. Bliss, of New Haven, Connecticut. It is hoped to hold international meetings every few years, and all members will receive the journal *Biometrics*. For the purpose of more local activities, the Society is organised into regions, of which it is proposed that a British Region shall form one. A provisional committee, under the chairmanship of Dr. J. W. Trevan, vice-president for the Region, is now engaged in drafting proposals for the regional organisation and activities, which it is intended will primarily provide a means of bringing together all those biologists and biochemists who are interested in the application of quantitative methods, with the statisticians and mathematicians who can co-operate in developing these methods. It is hoped shortly to present these proposals to an inaugural meeting of the Region. Further information can be obtained from the Regional Secretary, Dr. K. Mather, of the John Innes Horticultural Institution, London, S.W.19.

Breeding of Avocets in Britain

PRIOR to 1938, when two pairs of avocets were reported to have nested in Ireland, ornithological records contained no reference to the breeding of these birds in Britain for more than a century. During the summer of 1947, however, two small colonies of avocets (*Recurvirostra avosetta*) established themselves in East Anglia. According to P. E. Brown and E. Lynn-Allen (*British Birds*, 41, No. 1, January 1948), nine pairs of adult birds, of which at least seven pairs nested, were present during the breeding season. Altogether sixteen young birds were known to have reached the free-flying state. The Royal Society for the Protection of Birds has already taken measures to ensure that the birds will be adequately safeguarded should they return in 1948.

School Ecological Studies: Blundell's Scientific Publication

THE second number (1947) of the *Magazine of the Blundell's School Science Society* is, like the first, worthy of special note since it has carefully avoided the usual mistake of becoming a rather extravagant, even useless, potpourri of miscellaneous information and has again developed a theme—that of ecology. In fact, it is a good though elementary collection of articles mainly of ecological interest. In an article on "Butterflies of the Tiverton Area", M. A. Lyne describes twenty-seven species found within a ten-mile radius of Blundell's School. P. R. Freeth's interest lies mainly in bird watching and bird ringing, and records that the British Birds Marking Scheme was revived at the School in 1947 after a lapse of eight years. Thirty-nine birds were ringed. O. H. D. Portsmouth describes the flora of a local marsh meadow. The marsh is divided into a wet area dominated by *Carex panicea* and a drier area dominated by *Juncus communis*. This article gives the floral ecology in detail and reveals an extraordinarily sound grasp of the principles of ecological study by such a young author.

R. Honey reports on a survey of the marine algæ of Guernsey, giving a systematic list and dealing with ecological factors, distribution and relations between flora and habitat. G. O. Mackie confines himself to a more intensive ecological study of the flora and fauna of rain gutters. Other articles, all ecological in approach, are the animal ecology of a field drainage scheme by J. S. Miller, some factors affecting the distribution of the may-fly by R. H. Champion, fauna of a stream by E. W. Sturton, and observations in bird territory by J. A. Shepherd. The entire publication reveals a sound biological training, indicates that the young students are stimulated to a healthy enthusiasm (they are fortunate in that their school is situated in a biologist's paradise), and offers its contributors a rare opportunity for training in setting out their observations, results and conclusions concisely and accurately.

Quarterly Journal of Experimental Psychology

THE Experimental Psychology Group, a small private society the membership of which is drawn from the teaching and research staffs of British universities and research institutions, and the object of which is to further the experimental and scientific study of psychological problems, has decided to found a new journal, to be known as the *Quarterly Journal of Experimental Psychology*. While the volume of scientific work within the general field of psychology and the neighbouring fringes of physiology, medicine, biology and physics has greatly increased within the past few years, publication has been severely restricted by lack of a journal devoted exclusively to these fields. Much work has appeared in journals representing other branches of science. The intention is to produce a small journal of high quality in which scientific psychological work, whether experimental or clinical, and whether carried out in psychological or in other research institutions, may find a focus and an outlet. The journal will be edited by R. C. Oldfield, of the Institute of Experimental Psychology, University of Oxford, who will be assisted by an editorial board of six other members of the Experimental Psychology Group, and it will be published by Messrs. W. Heffer and Sons, Ltd., Cambridge (subscription, 30*s*. a volume of four parts). It is hoped to produce the first part in March.

Submarine Gravity Survey in the English Channel

THE Department of Geodesy and Geophysics, University of Cambridge, is to make a gravity survey on board H.M. Submarine *Talent* in the English Channel during May. The project is being carried out under the auspices of the Royal Society with the full co-operation of the Royal Navy. The object of the expedition is to obtain information about the structure of the channel basin which should help in interpreting the relation of the geology of southern England to that of the Continent. The cruise will last for four weeks and cover the area between England and France from Plymouth to Hastings. H.M. Submarine *Talent* will be manned by her normal complement of officers and men of the Royal Navy, but three civilian scientific workers, Mr. B. C. Browne, Mr. R. I. B. Cooper and Mr. R. L. G. Gilbert, will also be on board. She will be equipped with special apparatus, some of which has generously been lent by the Danish Geodetic Commission. Accurate measurement of this kind can only be made under very steady conditions, such as those found by a submarine at a depth of 100–200 ft. This method of working was originally devised by the Dutch geophysicist, Prof. F. A. Vening-Meinesz, and has been widely used by him. Similar work has also been carried out by the United States, France, Italy, the U.S.S.R., Japan, and Britain. A British expedition in August 1946 on board H.M.S. *Tudor* surveyed an area from the north coast of Spain to the Rockall Bank. Besides valuable scientific results, the experience gained showed how the apparatus and technique might be improved.

The Berlin Herbarium

MR. A. H. G. ALSTON, of the British Museum (Natural History), writes: "I have received the following information from a correspondent in Germany: The portion of the herbarium, which was evacuated from Berlin to Bleicherode, has quite recently been handed over officially to the Berlin University, and deposited in the Russian sector of Berlin. It was generally believed in Germany that these collections had been transported to the U.S.S.R., but, in fact, they remained at Erfurt until 'the President of the Moscow Academy of Science decided not to take over German *Kulturgut*'."

Ramsay Memorial Fellowships for Chemical Research

THE trustees will consider in June applications for Ramsay Memorial Fellowships for chemical research, one of which will be limited to candidates educated in Glasgow. The value of each Fellowship will be £400 per annum, to which may be added a grant for expenses of research not exceeding £100 per annum, and it will normally be tenable for two years. Full particulars can be obtained from the Joint Honorary Secretaries, Ramsay Memorial Fellowships Trust, University College London, Gower Street, W.C.1, to whom applications must be forwarded not later than April 17.

Announcements

THE Linnean Society of London has awarded the Linnean Medal for the year 1948 to Dr. Agnes Arber, F.R.S., of Cambridge. The Medal will be presented at the anniversary meeting on May 24.

THE Council of the University of Bristol has made the following appointments in the Department of Physics, to take effect on the retirement of Prof. A. M. Tyndall at the end of the present session: Prof. N. F. Mott, to be Henry Overton Wills professor of physics and director of the Wills Laboratory; Dr. C. F. Powell, to be Melville Wills professor of physics; Dr. S. H. Piper, to be assistant director of the Wills Laboratory.

THE following elections to the Paris Academy of Sciences have been announced: André Boivin, *correspondant* for the Section of Rural Economy, in succession to the late M. Henri Vallée; and Dr. Theodor Mortensen, director of the Department of Invertebrates, Zoological Museum, Copenhagen, *correspondant* for the Section of Anatomy and Zoology, in succession to the late M. Edouard Chatton.

DR. E. W. FELL has been appointed senior assistant in metallurgy at the Bradford Technical College. He was educated at Haileybury and the Universities of Birmingham, Aachen and Cambridge, and has many years of varied experience in the practice of metallurgy.

AT the annual meeting of the Manchester Joint Research Council held on February 16, Sir Raymond Streat was elected chairman and Sir Charles Renold honorary treasurer.

THE Association of British Science Writers is now open to accept associate members. Associate membership is intended for non-professional science writers, that is, those who do not earn the major part of their income from science writing. Those interested should apply for particulars to the honorary secretary, Mr. Maurice Goldsmith, at 81 Hillside Gardens, Edgware, Middlesex.

SIR JOHN MYRES writes, referring to his review of "A Glossary of Greek Fishes" (*Nature*, Feb. 7, p. 185), "the words *weel* and *péganon*, which I queried as misprints, are both correct".

Animal Tissue Cells in Protein-Free Media

FEW attempts have been made to maintain (or grow) animal tissue cells in protein-free media, although it has been shown[1] that the low molecular weight substances of blood plasma are of the utmost importance for the life of tissue cells, which rapidly perish in dialysed blood plasma. It has further been possible[1,2], by the addition of a number of amino-acids together with glutamine, glutathione and hexose diphosphate to a medium containing only dialysed plasma proteins and dialysed embryonic extract, to obtain survival and growth of the cells. The few attempts made to devise completely synthetic media have met with only partial success because of lack of a suitable technique, and because very little is really known about the fundamental nutritional requirements of animal tissue cells during survival and growth.

M. R. Lewis and W. H. Lewis[3] obtained migration and growth of cells in hanging-drop cultures in media containing inorganic salts, dextrose or maltose, amino-acids and polypeptides. As they also obtained migration and growth in a medium containing inorganic salts only, there could, however, be no doubt that their results were complicated by insufficiently defined residual growth phenomena originating from the use of rather large tissue explants and small volumes of media. P. R. White[4] has recently, by means of a modified roller tube technique, obtained migration and growth of long duration in a synthetic medium containing a large number of substances supposed to be of importance for the maintenance and growth of animal tissue cells *in vitro*. The manner in which White prepared the tissue explants and placed them in the cultivation tubes does not seem to ensure, however, that the reaction of the cells was due solely to the constituents of the synthetic medium (cf. also ref. 2).

In order to be able to study the effects of some protein-free media, I have made use of hanging-drop cultures made according to the technique of Lewis and Lewis[3]. By the use of very small explants (of embryonic heart tissue; 8–9 day embryos) it apparently became possible to avoid contamination of the media by substances given off from the explants. The following results were obtained:

(1) In Tyrode solution no migration of cells was obtained, undoubtedly because a solution containing only inorganic salts and dextrose cannot maintain the life of animal tissue cells.

(2) Tyrode solution containing the following nine amino-acids was made up: *d*-lysine dihydrochloride (0·006 per cent); *d*-arginine (0·003 per cent); *l*-tryptophane (0·002 per cent); *d,l*-methionine (0·001 per cent); *l*-histidine monohydrochloride (0·001 per cent); glutamic acid (0·006 per cent); *l*-aspartic acid (0·002 per cent); *l*-proline (0·002 per cent); *l*-cystine (0·0006 per cent), (cf. ref. 1). Zones of migrating cells were formed around the explants. The number of migrated cells showed great variation (from a few hundred to about 1,500 cells). The mitotic frequency was very low (about 1 per 4,000 cells). The cells survived two or three days, looking apparently normal. The addition of glutamine (0·05 per cent), glutathione (0·01 per cent) and hexose diphosphate (0·03 per cent) did not change the result.

(3) Dialysate obtained by dialysis of blood plasma (adult cock) against an equal volume of Ringer's solution (0·1 per cent dextrose). Large zones of migrating cells were observed (the number of migrating cells varying between a few hundred and more than 2,000). The mitotic frequency was very low (1 per 2,500). Dialysates of pig and ox serum have so far given no cellular migration.

A number of experiments have also been made, placing the tissue explants at the bottom of Carrel flasks (volume of medium 0·5–1 c.c., one explant in each flask). The *p*H was adjusted to 7·6–7·8 by regulation of the amount of carbon dioxide present. The large volume of the medium, and frequent renewals, made it possible to keep its composition constant—this is scarcely possible in hanging-drop cultures for any long period of time.

In this way, survival of zones of migrated cells in the amino-acid mixture (in Tyrode solution) or in plasma dialysate up to ten to twelve days was achieved; no migration of cells could be obtained in Tyrode solution alone. It is, moreover, possible to isolate zones of migrated cells placed at the bottom of Carrel flasks, the original explants being removed after one or two days.

Using the procedures described here makes it possible to study the effects of protein-free media on tissue cells *in vitro*.

Failure of Sulphanilamide to Inhibit Calcification of Bone

BENESCH and co-workers[1] have reported almost complete absence of calcification in the bones of rat fœtuses at term, following administration of large doses of sulphanilamide and sulphapyridine to the mothers during the last seven to ten days of the gestation period. Their report was based upon hæmatoxylin-staining of decalcified bones, with the reservation that this method might not be reliable, and upon X-ray examination of the bones of the fœtuses from sulphonamide-treated rats, no mention being made of control observations upon normal fœtuses. The results of observations upon mice were stated to be equivocal.

We have administered sulphanilamide to pregnant rats under conditions similar to those reported by Benesch *et al.*, and have observed the new-born rats from both treated and untreated mothers by positive staining of bone salt in undecalcified bones and by X-rays. Our observations do not confirm those of Benesch *et al.*

Four pregnant rats received 720 mgm. of sulphanilamide/kgm./day during the latter 5, 7, 11 and 16 days, respectively, of pregnancy. Three new-born rats of each litter were examined by X-rays and autopsied within fifteen hours after birth. X-ray films were made with 10 m. amp. current and 1 sec.

exposure; the technique of development was identical for all. Undecalcified histological preparations stained by the von Kóssa method, as described by McLean and Bloom[2], were made from sagittal sections through the knee joint. Litters from five normal untreated rats were similarly examined and served as controls.

The findings in all these animals were comparable to those described by Bloom and Bloom[3] in embryonic and new-born rats, and we have been unable to detect any differences between rats born from treated and untreated mothers. It is true that there are "striking defects in various parts of the skeleton" of new-born rats, as shown by X-ray examination; but these defects are not peculiar to the offspring from mothers treated with sulphonamides.

Benesch *et al.* began their work with the hypothesis that sulphanilamide, which inhibits carbonic anhydrase, might interfere with calcification, with the expectation that sulphapyridine, which does not have any effect on this enzyme, would have no effect on the deposition of bone salt. In view of their reported findings, which appeared to indicate that both sulphonamides inhibited calcification, they offered the interpretation that this effect was due to inhibition of the activity of bone phosphatase. Silver and Golding[4] have shown that bone phosphatase is inhibited by sulphonamides *in vitro*, but the concentrations required (250–1,500 mgm. per cent) and the degree of inhibition (50 per cent or less) would make it extremely unlikely that this mechanism could have physiological significance.

This work was supported by a grant-in-aid from the United States Public Health Service, Research Grants Division.

Bilirubin-Serum Protein Complexes and the van den Bergh Reaction

RECENT work by N. H. Martin[1], showing complex formation between bilirubin and the α-globulin as well as the albumin components of plasma, is not only of great theoretical and practical significance from the point of view of the physical chemistry of the proteins, but also may have important implications regarding the interpretation of the van den Bergh reaction. The binding of bilirubin to different plasma protein fractions might be related to the alleged two forms of bilirubin postulated by many workers to explain the different types of direct van den Bergh reaction.

We have examined a small number of jaundiced sera by the electrophoresis technique and can confirm Martin's findings that a small but definite fraction of the bilirubin migrates with the α-globulin fraction, in addition to the migration of the main fraction of the bilirubin with the albumin. In all cases, bilirubin migrated in much the same proportions with the albumin and α-globulin fractions respectively, whatever the nature of the jaundice or the type of direct van den Bergh reaction. One of the jaundiced sera we examined was obtained from a patient with retention jaundice and contained 16·2 mgm. bilirubin per 100 ml., gave an almost completely negative direct van den Bergh reaction and a direct–indirect quotient (*D.I.Q.*)[2] of 9 by the 30 min. Malloy and Evelyn method. The bilirubin of this serum behaved in the electrophoresis apparatus in precisely the same way as bilirubin of sera from patients with obstructive jaundice or acute hepatitis and containing similar amounts of bilirubin but giving typical positive direct van den Bergh reactions and *D.I.Q.* values greater than 50. We are therefore compelled to conclude that the binding of bilirubin by different fractions of the plasma proteins bears no direct relationship to the nature of the direct van den Bergh reaction.

Alkaline Phosphatase in Fish Gut

SINCE Gomori[1] and Takamatsu[2] adopted a histochemical test for the demonstration of alkaline phosphatase, many investigators have examined the distribution of the enzyme in animal tissues; the majority, however, employed material from mammals.

I have recently been studying the distribution of the enzyme in the alimentary tract of certain freshwater fishes, namely, three species of the family Cyprinidæ. The results are not without interest. For example, the concentration of the enzyme varies from species to species as well as in the various segments of the otherwise comparatively uniform intestine. The sites of activity of the enzyme are the free border of the absorptive cells, and the granular cells which are found in the submucosa and which invade the intestinal epithelium (these are known to be derived from granulocyte leucocytes, Duthie[3]). The enzyme occurs also in the connective tissue, blood vessels, and in the stratified epithelium lining the buccal and pharyngeal cavities. The presence of the enzyme in the Golgi zone of the absorptive cells is not a constant feature of these fish, contrary to what Emmel[4], and Deane and Dempsey[5] have found in certain mammals.

It is generally accepted that the enzyme is involved in a phosphorylation process of glucose[6,7]. Its presence in the stratified epithelium, especially concentrated in the stratum germinativum, is therefore of interest; and it is suggested that in such epithelium, where the intercellular substance is very scanty, glucose may pass into the epithelium by a chemical process of phosphorylation, initiated by the enzyme secreted at its base, rather than by diffusion.

Gomori and Takamatsu incubated the sections with the substrate at 37° C., which corresponds roughly to the body temperature in mammals. In a few experiments, incubation has been carried out at 28° C. with fish material, and very good results were obtained; the optimum temperature for the enzyme in cold-blooded vertebrates is not necessarily the same as in mammals. This, and also the optimum pH, needs further investigation.

In view of these facts, and that our knowledge of the comparative histochemistry of the lower vertebrates is slight, a comparative study of the distribution of alkaline phosphatase in the alimentary tract of lower vertebrates, and an experimental investigation of the conditions under which the enzyme acts in these animals, are needed, and seem likely to yield results of considerable interest in the histochemical field. The work is now proceeding, and it is hoped to publish a full account in the near future.

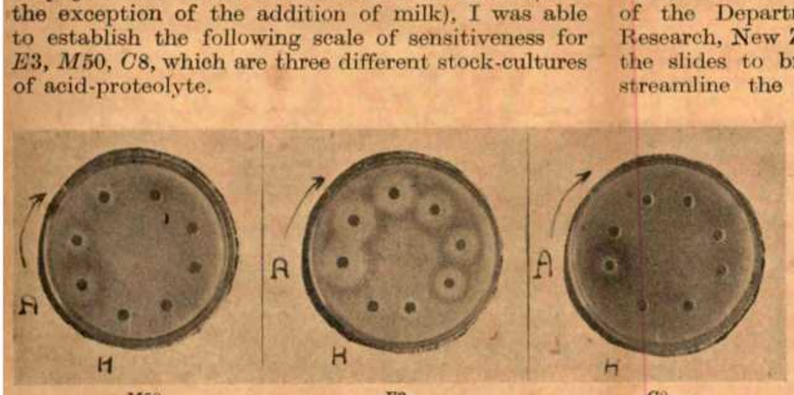
Behaviour of Gorini's Acid-Proteolytic Lactic Cocci with Penicillin

THE study of penicillin resistance is interesting particularly if observations are made on the usual substratum of the bacteria, that is, in the optimum conditions of life. Basing my work on the observation of C. Gorini[1] that the colonies of his cocci inoculated in agar broth with milk form around each colony a transparent zone due to proteolysis that has dissolved the casein, I carried out tests by the following method: the Petri plates, containing 15 ml. of melted agar broth flooded with 20 per cent of milk, were inoculated with 1 ml. of a 48-hour milk-culture of the stock in question. Holes were made on the slides, as is done in routine testing of penicillin, and in each was put a drop of serial dilutions of crystallized sodium penicillin *C.S.C.* The method proved simple, quick and very sensitive. The zones of inhibition showed themselves as cloudy circles where the casein had not been proteolysed, whereas the rest of the plate became clear, the vitality of the bacteria there being shown by their proteolytic power.

Comparing the diameter of the circles observed with the acid-proteolytes and those obtained with *Staphylococcus aureus* under the same conditions (with the exception of the addition of milk), I was able to establish the following scale of sensitiveness for *E*3, *M*50, *C*8, which are three different stock-cultures of acid-proteolyte.

Staphylococcus aureus Oxford	Acid-proteolytic lactic cocci Gor.		
	*E*3	*M*50	*C*8
1	1/5	1/100	1/200



*M*50 *E*3 *C*8

BEHAVIOUR OF THREE STOCKS OF ACID-PROTEOLYTIC LACTIC COCCI GOR.

In the holes of every plate there are the following serial dilutions of penicillin: O.U./ml.: from *A* to *H*, 100, 25, 10, 2, 1, 0·4, 0·2, 0

This method, devised for the fuller study of the properties of the acid-proteolytes, has led to the following interesting observation: around all the cloudy circles of inhibition, zones of increasing clearness are noticed in regard to the rest of the slides, which I interpret as showing greater strength of proteolytic activity of the bacteria in these places.

As the photographs show, a background zone of proteolytic activity can be seen in the plates, a circle (immediately around the drop of penicillin) of non-activity, and a larger circle (around the first) of the maximum proteolytic activity. The most plausible explanation is that a zone of different bacterial activity is being dealt with. I have seen multiple concentric circles with *Staphylococcus*, too; but in the case described above they are of a regularity and clearness that require fuller study.

The investigation shows that the sensitivity to penicillin of the Gorini acid-proteolytic lactic cocci stock examined (in conformity with their great variability as stated by C. Gorini[1]) varies between a minimum of 5 O.U. for the most sensitive and a maximum of 200 O.U. for the most resisting. Tests on the liquid of a four-day milk-centrifuged culture show very little inhibitory power on penicillin not due to penicillinase but to heat-resisting substances.

Aerobiology on Commercial Air Routes

WHILE I was a passenger from New Zealand to the United Kingdom in September 1947, I was able to expose microscope slides on a stick held out from commercial flying boats, and I trapped as many as 143 pollen grains and 273 fungal spores on 7·5 sq. cm. of adhesive surface exposed for five minutes at 140 knots (about 160 m.p.h.). Proctor[1] outlines a number of complicated constructions for exposure of slides from aeroplanes; but the simple method I have used makes it possible for biologists travelling as ordinary passengers on commercial aircraft to contribute to our knowledge of aerobiology. The method is due to a suggestion by Mr. E. A. Madden of the Department of Scientific and Industrial Research, New Zealand, to run a leading wire before the slides to break up the pressure cone, and to streamline the stick behind in order to prevent turbulence from increasing its apparent width. At the lower speed of their aircraft, this may not have been necessary for the single slides of Polunin *et al.*[2] and of Stakman *et al.*[3]; but the larger surface of Stakman's multi-slide trap may have required some such provision, and hence its poorer performance. My exposures were made through the astro-hatch of the Empire-class flying boat *Aotearoa*, over the Tasman Sea, and through the window of the steward's pantry on the Hythe flying boat, *Hobart*, thereafter.

Using nutrient agar (a potato-dextrose agar with addition of protein, etc., used in and supplied by the Laboratory of the Wellington (N.Z.) Public Hospital; commonly used for *Brucellus abortus*, and recommended for a wide range of organisms) on the slides, and establishing controls over every phase of the operation, I have obtained very few colonies growing: a different strain of *Cladosporium herbarum* Link ex Fr. (kindly identified by Mr. H. A. Dade, assistant director, Imperial Mycological Institute (letter dated Oct. 14, 1947)) over each of the Gulf of Carpentaria, the Island of Sumbawa and the Strait of Bonifacio, while 200 miles off Sydney, over the Tasman Sea, some eight colonies (of four or five different kinds) of organisms appeared (identifications are awaited from Sydney). The methods used may have missed some possible colonies, but this scarcity of viable (on that agar) organisms (six other exposures were made, but without growths) contrasts with the profusion of growths on the Petri dishes (of unstated size) exposed by Polunin *et al.*[2] in the Arctic. Their still unwrapped dishes, however, were no control whatever for the probable contamination from the arm (sleeve ?) along which they slid the lid of the dish during exposures. My agar surface was about 10 sq. cm.

The chief results of my work will be from slides carrying an area of 7·5 sq. cm. of glycerine jelly, containing a little carbol fuchsin. Prepared in the way usual for allergy studies, where only large numbers are significant, these slides showed a little contamination. For studies such as the present one, where small numbers are significant, more rigorous methods of preparation should be used. The slides were stored under 'Cellophane' arranged so that successive removals left the remaining slides still protected from dust. A cover-slip was added after exposure. Out of the ten exposed slides and four controls, only the three from the Tasman Sea and one control have been examined in detail to locate the objects caught. An analysis of these slides is as follows:

Slide number and position	61, control covered at Cambridge	51, at 2,100 ft. 37° 08′ S.; 173° 40′ E. 50 miles off N.Z.	52, at 4,500 ft. 35° 58′ S.; 163° 00′ E. 700 miles off Aust.	53, at 4,000 ft. 34° 40′ S.; 155° 20′ E.† 210 miles off Aust.
Pollen grains	4	2	16	143
Fungal spores	1	3	14	273
Pieces of hypha	0	1	2	26
Other biota*	8 (+ 15)	11 (+ 17)	14 (+ 19)	47 (+ 11)
Total	28	34	65	500

* Mites', etc., eggs were reported present at time of preparation. They are represented by the figure in brackets and show no correlation with exposure.

† The exposure was made 15 minutes later than this position.

Slide No. 51, so near land, should be regarded as showing no catch in view of the control slide, No. 61, the pollen grains on both being likely contaminants from the laboratory where the slides were prepared. On the meagre information available, Dr. R. G. Simmers, acting director of the Meteorological Service, New Zealand, suggests (letter dated Oct. 22, 1947) that the wind of direction 200° at the position of the slide had "likely" crossed New Zealand from south-east to north-west (that is, at a direction of 135°). Harmonizing these two directions would bring the "crossing" in the neighbourhood of the Cook Strait region. If this were so, it would explain the absence of particles here, a contrast with Erdtman's[4] near-land experience on a North Atlantic steamer crossing.

Slides Nos. 52 and 53 represent 75 and 875 pollen grains, respectively, and 70 and 1,680 fungal spores, respectively, per 100 c. metres of air, assuming that the volume of space traversed represents the volume of air 'swept'. This is a great contrast with Erdtman's[4] 0·7–18·0 (pollen and fern spores) for his North Atlantic crossing in May–June, 1937.

The routes of the air masses to which these two slides were exposed have also been indicated by Dr. Simmers. For No. 53 the air crossed the coast of Australia about 100 miles south of Sydney. For No. 52 it possibly crossed southern Victoria or even came through Bass Strait. The pollen of *Callitris* sp. was represented by 84 grains on No. 53 and 5 grains on No. 52. The flowering times and distribution of *Callitris* species, according to Ewart[5], would satisfy the route for air met by No. 53, but would require for the air of No. 52 a more direct route over southern New South Wales or a curved route from north-west Victoria or South Australia. The first route would give transport of 900 miles approximately (200 over land, 700 over sea) from southern New South Wales. The second route would give transport of about 1,200 miles, at least, from north-west Victoria. The lesser distance is distinctly greater than the 500–700 miles, depending on interpretation of wind, given by Meier[6] for living spores over the Caribbean Sea.

Other interesting objects observed were numerous spores of *Cladosporium herbarum*, many multicellular conidia of Fungi Imperfecti, about twelve rust (Uredinales) spores on No. 53, and hyphæ probably of sooty mould fungi. It should be noted that even for slide 52 the particles still had 4,500 feet to fall.

These incomplete data and simple methods are brought forward to encourage others to follow suit if opportunity arises in the form of an aeroplane journey. It is interesting also to note the possibility of employing pollen studies for elucidating paths of air masses in areas deficient in meteorological recordings, such as the Tasman Sea region.

I am indebted to the airway companies concerned and the crews of the aircrafts for their generous co-operation, and to friends who helped in the preparations. Full acknowledgment will be made in the detailed account being prepared.

An Undescribed Structure in the Rodent Rhinarium

DURING a survey of the detailed sculpturing of the specialized naked integument of the mammalian rhinarium, what appears to be a hitherto undescribed tactile organ has been noted in almost all members of the Rodentia examined, except the Hystricomorpha. Developed in incipient form in the Lagomorpha, it becomes more defined in the Sciuromorpha, but attains its highest differentiation in the Myomorpha.

In most rodents the naked rhinarium is comparatively restricted and frequently partially or completely overshadowed by folds from neighbouring hair-clad parts of the muzzle. But the internarial septum and the immediate margins of the nares are generally free from hairs or at least glabrous. At the medial angle of the narial opening is a more or less raised area of rounded or oval outline. Relatively little raised in *Lepus* and *Oryctolagus*, it becomes more prominent in Sciuromorpha and Myomorpha, encroaching upon the internarial region sometimes to the extent of being separated from its fellow merely by a median vertical sulcus.

The surface of the above-mentioned elevation is variously sculptured in different species. In *Sciurus* it is merely papillated. In the Lagomorpha the anterior two thirds is finely papillated, the papillæ being arranged in longitudinal rows, but on the posterior third the papillæ appear to have fused to form a series (five to six) of longitudinal ridges closely simulating the papillary ridges of the Primate cheiridium. In the Myomorpha the whole surface is definitely ridged in the same manner as the Primate hand, the pattern being generally a simple one. In *Rattus norvegicus*, for example, there is an arrangement in arches, with their summits directed medially. In at least one genus, *Lophiomys*, a suspicion of a triradius was observed. It remains to be seen what degree of individual variation, if any, occurs in the pattern. The nature of the nerve endings in this specialized apparatus will also require investigation.

Details are being published elsewhere.

Chromosome Number of *Cardamine pratensis*

THE chromosome number of *Cardamine pratensis* L. has been investigated by a number of cytologists and, as is shown in the table, several numbers have been reported.

Author	Locality of specimens	Somatic chromosome number
Manton[1]	Cambridge	*c.* 32
Manton[1]	Double varieties from botanic gardens	*c.* 64
Lawrence[2]	Merton, London	30
Flovik[3]	Spitsbergen	64
Lövkvist[4]	Southern Sweden	30, 56, 60, 64, 68, 72 and 76

The work of Lövkvist is of considerable interest in that he found a relationship between chromosome number and dampness of habitat; plants with 30 chromosomes being found in the higher parts of meadows, plants with 56–68 chromosomes being found in the lower parts and plants with 72 and 76 chromosomes near or in the water. This work also suggested that chromosome counts of wild British plants might be interesting.

Plants from three localities near Cambridge (Grantchester Meadows, Milton and Wicken Fen) and one plant from High Lane, Cheshire, have now been examined. All these have been found, from second metaphase plates of pollen mother cells (Feulgen stained squashes), to have a chromosome number of $n = 28$ (that is, a somatic chromosome number of 56). All these plants came from rather wet situations, and it also appears that Lawrence's material from the John Innes Horticultural Institution's garden came from a rather dry place. There thus seems to be some confirmation of Lövkvist's findings.

The systematic position is somewhat obscure and Lövkvist goes no further than suggesting that "*Cardamine pratensis* and *C. dentata* are probably the extremes in a series of types having more or fewer traits from the one or other of the two species". Lövkvist also states that he only found meiotic irregularities in forms having 30 chromosomes. In my material, however, two univalent chromosomes were common in the 56 chromosome plants.

My thanks are due to J. P. Cooper for the High Lane plant and to V. Chapman for making the cytological preparations.

Chronometric Observations of the Song of *Fringilla cœlebs* Linn.

DURING the 1946 breeding season of the common chaffinch (*Fringilla cœlebs* L.), 5,468 observations were obtained of the song interval, that is, the time taken by the cock bird to utter his characteristic sequence of notes[1]. A split-second hand chronometer was used to record the duration of the interval to the nearest tenth of one second, and a correction was applied to eliminate the personal equation of the observer. Corrected times are considered accurate to ± 0·1 sec. No particular care was taken to ensure that successive records were obtained from the same birds, since it was desired to examine a typically representative cross-section of the local chaffinch population. Recording was made under a variety of weather conditions to assess the possible influence of certain meteorological factors on the duration and frequency distribution of the interval value defined previously.

The chief results of analysing the complete data may be briefly summarized as follows:

(i) The mean value of the song interval, based on 10-day averages of all the observations, is found to be 1·9 ± 0·1 sec. The 10-day average values exhibit a well-marked seasonal fluctuation yielding a single, flat maximum of amplitude 0·6 sec. This trend is shown by the data of Table 1.

TABLE 1. SEASONAL MARCH OF AVERAGE SONG INTERVAL

Days from onset of singing	5	15	35	55	75	105	125	135
Mean duration of song interval in tenth-sec.	15	16	17	20	22	22	20	18

By interpolation it is found that the maximum value of the mean song interval is attained by about the ninetieth day after the onset of singing. Both previous to, and subsequent to, this date the interval is shorter, the rate of variation being most rapid towards the end of the season (the marked rise observed between the thirty-fifth and fifty-fifth days most probably resulted from an abnormally low air temperature during the preceding twenty days).

(ii) Of the four meteorological factors studied in conjunction with the chronometric records, relative humidity affects the song interval most markedly.

Thus a change from moderately dry to damp air (60 to 90 per cent *R.H.*) shortened the average interval value from 21 to 18 tenth-seconds, a variation amounting to three times the observational error.[1] Air temperature, degree of cloudiness and wind-strength were found to exert a significant, though less pronounced, influence on the magnitude of the song interval.

(iii) On grouping the recorded interval values in order of frequency of occurrence, a significant pattern is exhibited consisting of at least seven dominant values which range from 0·7 sec. to 3·7 sec., and are separated by an apparently constant difference of 0·5 sec. This distribution is illustrated by the data of Table 2, where the maximum frequency of occurrence has been arbitrarily chosen as 100.

TABLE 2. FREQUENCY DISTRIBUTION OF DOMINANT INTERVALS

Days from onset of singing	Dominant interval (tenth-seconds)						
	07	12	17	22	27	32	37
5	25	100	33	25	0	0	0
75	0	8	78	100	50	8	3
135	0	26	100	44	6	0	0

The occurrence frequency of the dominant intervals undergoes a systematic fluctuation in step with the seasonal cycle of the male bird, low values occurring around the dates of onset and cessation of singing; while higher values are restricted to the period which corresponds closely with the maximum phase of sexual activity. The causes underlying the changes just described are, in all probability, highly complex. It is hoped that other workers, more qualified to appreciate the zoological aspects of the problem, may be led to undertake further research, preferably using a microphone and electronic time-base to record the song interval objectively.

Earliest Known Prehistoric Industry

MR. J. E. SAINTY and the late Mr. Reid Moir have reported the occasional finding, in the Sub-Crag deposits of Norfolk and Suffolk, of flint flakes which they ascribed to human manufacture. Being so sporadic, these flakes have been doubted by some (including myself) as definite indication of the presence of man or of a man-like form. My own doubts have been completely dispelled by the discovery of an excellent flake industry at this horizon occurring at five different sites near Cromer.

The industry consists mostly of side-bulb flakes produced in two fashions. They have been struck freely from undifferentiated asymmetrical and pebble cores, of the Clactonian form I have described elsewhere as the most primitive; or they have been produced by the bi-polar technique, splitting a fresh flint cobble by placing it upon another as a stock and striking with a third as a hammer. (These techniques should not be confused with the peculiarly misnamed 'block-on-block technique' said to be typical of the free-flaking Clactonian *sensu stricto*.) Most of the flakes have, necessarily, much cortex remaining on the reverse surface, but some show preparatory working associated with pebble cores.

Retouch is always from the flake surface, either free, with small 'running' flake scars, or step, closely similar to the typical Moustierian. Indeed, one specimen shows a perfect convex working edge as good as most Moustierian side scrapers. Other forms of working edge are deep and shallow single notches, points, double notches and abrupt-nosed ends. Small elongated cobbles, broken across, have been retouched on the scar edge like the so-called Darmsdenian, and large simple and asymmetrical cores have been used as hammers and choppers. One site, 13 ft. by 2 ft. 4 in. deep, has yielded an assemblage of more than three hundred flakes and tools distinctly reminiscent of the modern Tasmanian. I may add that my selection was most rigorous, involving the rejection of all pieces not certainly flakes, or showing flake scars.

The stratum, resting on Chalk, is a sub-aerial accumulation of flint cobbles weathered out over a long period and held together by sand and occasional clay, and is immediately overlain by the marine Weybourne Crag and by the Cromer Forest Bed series undisturbed with, in places, nearly 200 ft. of Pleistocene boulder clays, conglomerates, gravels, sands and loess-clays yielding palæolithic, and on top, later artefacts. Reid Moir traced the horizon beneath the Red Crag of Ipswich, making it the equivalent of the 'Stone Bed'. If this is so, the industry is pre-Pleistocene, assuming the base of the Pleistocene to be the Red Crag, the equivalent of the Rousillon, Astian and Tatrot, first glacial, and the Norwich Crag the equivalent of the Séneze, Villafranchian and late part of the Tatrot (Pinjor being first interglacial). The industry cannot be later than first glacial, but on several grounds it is most likely pre-Pleistocene.

We may confidently believe that here in East Anglia we have the most extensive sequence of prehistoric remains, and by far the earliest 'man'-made industry known to archæologists and geologists, opening up a new field of speculation on the antiquity of man.

Combined Radar, Photographic and Visual Observations of the Perseid Meteor Shower of 1947

DURING the past two years, considerable attention has been given to the radar reflexion from the ionization produced by meteors in our upper atmosphere. Significant results using frequencies of 2·7–212 mc./s. have been published by a number of investigators in both Britain and the United States[1]. In these papers there has been a general lack of any large quantity of correlated visual data giving the accurate times and positions of the meteors in the sky.

In August 1947 the Dominion Observatory in Ottawa and the National Research Council of Canada collaborated in an effort to secure correlated radar, visual and photographic records of meteors. The radar equipment was designed and operated by the National Research Council; the visual and photographic programmes were carried out by the Dominion

Observatory. The radar operated on 32·7 mc./s., with 150 kW. peak power, 8 microsec. pulse width, and receiver sensitivity of 5 × 10^{-14} watt. Both transmitter and receiver employed simple horizontal dipoles oriented north–south. An *A*-scope display was used for monitoring, while a range–time display on a long-delay screen cathode ray tube was employed for recording and photographing the echoes. Visual meteors were plotted and timed to the nearest second by six experienced observers. The direct and spectrographic cameras were equipped with a synchronously driven rotating shutter covering the lens ten times per second. The radar transmitter and receiver and the main visual and photographic stations were at the radio field station of the National Research Council, four miles south of Ottawa. A secondary visual and photographic station was operated at Luskville, Quebec, twenty-two miles distant. In a total of approximately thirty hours of observation on the five nights, August 9–14, 3,700 radar echoes, 1,100 visual meteors, and 20 meteor photographs were recorded.

A total of 101 radar echoes with durations of 5 sec. or longer coincided in time (mean effective time difference 1·5 sec.) with the brighter visual Perseid meteors, mean apparent magnitude 0·5. Statistical considerations indicate that not more than three of the above number might be chance coincidences. The mean echo duration was longer for the brighter meteors, and the correlation between the radar range and the visual altitude indicated that the radar echo originated at the position of the visual meteor. If α is defined as the elongation from the radiant, meteors moving head on will have $\alpha = 0°$; those moving at right angles to the line of sight, $\alpha = 90°$. The distribution of this group of meteors with respect to α was fairly uniform, being roughly proportional to the corresponding area of visible sky (see Table 1).

TABLE 1. DISTRIBUTION OF METEORS WITH RESPECT TO α

α	0°		10°		20°		30°		40°		50°		60°		70°		80°		90°		100°		110°		120°		130°
No.		3		4		5		5		13		11		15		13		10		13		1		6		2	

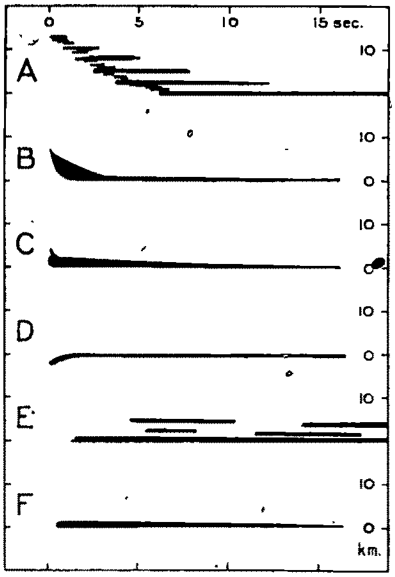
The corresponding echoes were divided into six empirical types, based on their appearance as photographed on the range–time display. The general form of each type has been sketched in the accompanying diagram. The average characteristics of the echo types have been listed in Table 2.

TABLE 2. MEAN CHARACTERISTICS OF RADAR METEOR ECHOES

Type	No. of meteors	Elongation from radiant (α in deg.)	Apparent visual magnitude	Echo duration (sec.)	Range (km.)	Total change in range
A	7	47 ± 2*	0·4	35	126	13
B	15	72 ± 2	0·9	17	140	7
C	4	74 ± 3	0·6	19	132	5
D	12	94 ± 2	1·0	23	171	3
E	19	50 ± 3	− 0·4	63	150	
F	44	5 to 125	0·7	26	160	

* Probable error of the mean.

The following additional observational facts appear evident from an examination of the echo photographs. Two basic types of echo seem to be present: (1) An echo which shows a continuous change in range, either decreasing or increasing, and which appears simultaneously with the visual meteor. Velocities deduced from this type of echo average well below the Perseid velocity of 61 km./sec., and the echo is generally restricted to meteors with α between 60° and 120°.



(2) A long-enduring echo at a discrete range (for brighter meteors several of these echoes at different ranges) which appears after the visual meteor with delays ranging from 1 to 12 sec. and which is present for all the meteors considered.

The total change in range found for the first type of echo decreases as α approaches 90°. It corresponds consistently with reflexion from a meteor path-length of about 20 km. For meteors with α near 90°, there is little or no spread in range and, though both the basic types of echo may be present, it is difficult to resolve them. The overall mean height for echoes of the second type was 99 km. and the average height difference between two echoes from the same meteor was 5 km.

Radar echoes lasting less than 5 sec. were twelve times as numerous as those of longer duration; but for these short echoes there was no significant correlation with the visual meteors in time of appearance. A total of fifty-four meteors, first magnitude and brighter, gave no echo at all on the radar.

The data presented above indicate that the strong, enduring radar reflexion from meteors is not restricted to the neighbourhood of the point where the meteor is travelling perpendicular to the line of sight. Hence, an explanation other than the geometrical one proposed by Hey, Stewart, Lovell and others must be sought to explain the discrete ranges observed. It seems logical to assume two different mechanisms for the production of the effective radar targets. The theory outlined by previous investigators would, with some modifications, account for the first basic echo type. To explain the second type a reasonably satisfactory phenomenological theory can be evolved by postulating the existence of discrete layers (fine structure) in the region in which the meteors appear. These layers are more highly susceptible to ionization from some agency (for example, ultra-violet light emitted by the meteor) than are the inter-layer spaces. Delays in the growth of the layer ionization clouds can account for the principal phenomena observed in the long-enduring echoes and might, for the short echoes, explain the lack of coincidence in time with the visual meteors. The layer theory is consistent with the sharp cut-off at minimum slant range found by Appleton and Pierce for the Giacobinid meteors.

It is not feasible to attempt to compress all the experimental data or the tentative theoretical conclusions into a short letter of this nature.

Soc.*, **59**, 461 (1947). Hey, J. S., and Stewart, G. S., *Proc. Phys. Soc.*, **59**, 858 (1947). Papers by Prentice, J. P. M., Lovell, A. C. B., and Banwell, C. J., and by Lovell, A. C. B., Banwell, C. J., and Clegg, J. A., *Mon. Not. Roy. Astro. Soc.* (in the press).

THE results obtained by Dr. Millman and his colleagues represent an important contribution to the study of the complex radio echo phenomena which are observed on wave-lengths longer than 8 m. Recent unpublished British work has a significant bearing on some of the issues raised and a short summary may be appropriate.

Effect of Radio Wave-length. Simultaneous observations on two or more wave-lengths have been made of the transient echoes originating in the 100 km. region of the atmosphere, from which it appears that a striking change occurs as the wave-length is decreased from 8 m. to 6 m.[1]. Above 8 m. a very large number of radio echoes are observed independently of the presence of a major meteor shower of the 'visible' type. These echoes show a marked diurnal and seasonal variation[2,3], and are believed to be due to a uniform distribution of minute dust through which the earth is passing. As the radio wave-length is decreased, this high echo-rate disappears, and, on 6 m. and less, the transient echoes arise only from the meteors associated with the visible streams emanating from definite radiants.

Aspect Sensitivity and the Scattering Process. On wave-lengths less than 6 m. the main radio echo is obtained only when the meteor crosses the perpendicular from the station to the trail. This is immediately evident when observations are made with a highly beamed aerial system. Thus, near the peak of the great 1946 Giacobinid shower, a directional aerial system was turned into the radiant instead of at right-angles to it, and the echo-rate fell from 50 per minute to less than 0·1 per minute, although at that time the sky appeared to be full of meteors[4]. This aspect sensitivity, and the change in scattered power with wave-length from the same meteor trail, can be explained if the electrons are created by the meteor in the form of a long column of diameter small compared with the wave-length[5]. It has been realized, however, that this picture does not succeed in giving a satisfactory account of the much more complicated phenomena in the wave-length range greater than 8 m., and as Dr. Millman and his colleagues suggest, additional scattering processes must be invoked to explain the high echo-rate from invisible meteors, and the lack of aspect sensitivity.

It seems clear that in the present state of our knowledge the astronomy of the meteor streams can only be studied satisfactorily on wave-lengths less than 6 m., where the aspect sensitivity of the trails can be used to delineate radiant points by such methods as devised by Hey and Stewart[6], and Clegg[7], and where the observed echo-rates bear a very close relation to the visible meteor-rate.

The complex phenomena on longer wave-lengths are not yet understood, and further information of the Canadian experiments will be awaited with much interest.

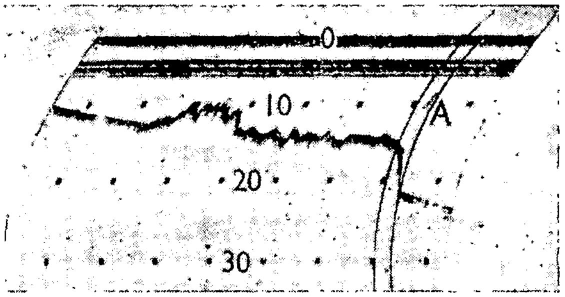
A Submerged Ancient Cliff near Plymouth

ECHO soundings, made on the Marine Biological Association's research vessel *Sabella*, have revealed a submarine cliff, suggesting an ancient shore line, about two miles south-south-west magnetic from Plymouth Breakwater Lighthouse (see record reproduced). The height of the cliff at the section is about 33 ft., its foot rests at about 22 fathoms below the level of low water springs, while the gradient is of the order 1 in 3.



PORTION OF ECHO-SOUNDING RECORD ON COURSE S.S.W. MAGNETIC FROM PLYMOUTH BREAKWATER LIGHTHOUSE

A vertical line below the ship is represented by an arc of a circle. The distance between two dots along an arc represents ten fathoms, while the distance between two dots along a horizontal line represents the passing of 3 min. or about 650 ft. run by the ship at a quarter speed

The record of the bottom landward of the submerged cliff in 15 fathoms or less is irregular, suggesting a surface of sub-aerial denudation which has not yet been completely covered with recent deposits. Seaward of the cliff the record, with others, shows a gently sloping smooth platform suggesting a wave-cut beach possibly covered with some recent sediments. Sections across the submerged part of the Eddystone show a very rugged topography; nonetheless, there are indications at several points of the foot of a wave-cut cliff at 24 fathoms.

The formation of such a cliff would seem to need a fairly prolonged stand of the sea at a level about 22 fathoms (40 m.) lower than that of to-day, or perhaps a few fathoms lower still. If similar cliffs exist elsewhere in the English Channel, their further study may help to solve problems of sea-level during the regressions of the sea in the Pleistocene Ice Ages.

Directly above the cliff at the point marked *A* the record of a shoal of fish may be seen. The fish are reminiscent of birds soaring above a cliff in an ascending current of air. The time was within five minutes of low water at Devonport.

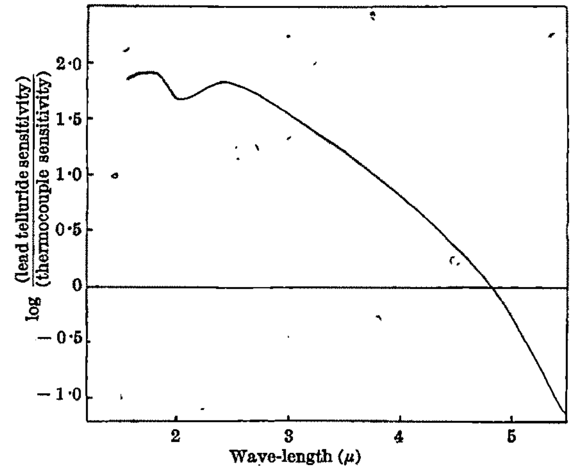
Lead Telluride Cells for Infra-Red Spectroscopy

FOLLOWING the successful development[1,2] of lead selenide photoconductive cells for the detection of infra-red radiation, we have now extended this work to lead telluride. It was known from very incomplete information that experimental cells of this material were made in Germany during the War[3] and showed some response as far as 5·8 μ, that is, considerably farther than lead selenide. However, no information was available to us on the method of preparation, nor on their performance, and it may be presumed that the absolute sensitivity was poor, in view of the widespread use in Germany of the lead sulphide cell in spite of its restriction to wave-lengths shorter than 3 μ.

As the evaporation method was used, one of the main problems was to find a window material for the base of the cell which would transmit radiation to at least 6 μ. After experimenting with various alternatives, including evaporation from small heating coils, an extremely simple solution has been found, namely, to make use of thin bubble windows similar to those used in certain ultra-violet work. It has been found that flat windows of glass approximately 20 μ thick transmit more than 90 per cent of any radiation between the visible and 8 μ, and that 'hemispherical' windows can be made which are sufficiently strong to withstand atmospheric pressure, and transmit freely to beyond 6 μ. Although some distortion of the beam occurs in passing through such a window, our results show that the effect of this on the performance of the cell is negligible.



The lead telluride cells show no photosensitivity at ordinary temperatures, and so far all the observations have been made at the temperature of liquid air. The response curve of one telluride cell to various wave-lengths is shown in the accompanying graph, in which the ordinate represents the logarithm of the ratio of the cell response to that of a Hilger–Schwarz vacuum thermocouple, the comparison being made in the same manner as for lead selenide[2]. It should be noted that at its maximum the sensitivity of the lead telluride cell is about a hundred times that of the thermocouple, that is, much the same as for the best lead sulphide cells[4]. Although the maximum of sensitivity shown by this cell lies between 2 and 3 μ, it is superior to a thermocouple up to 4·6 μ and some sensitivity is exhibited so far as 5·5 μ. As experience is gained with these cells, it may well be possible to control the position of maximum response and cause it to move to between 4 and 5 μ, as reported in the German work[3]. The time of response of these lead telluride cells is of the order of 10^{-4} sec., which is about the same as lead sulphide. It is important to note that the selenide cells which were much more rapid in response (about 10^{-5} sec.) were much less sensitive. It seems probable that there is a reciprocal relation between time of response and sensitivity for detectors of this class.

This note is primarily intended to indicate the potentialities of cells of this type for spectroscopic work, where they are clearly far superior to sulphide and selenide; full details of the method of preparation and of the properties of these cells will be published shortly.

It may be added, however, that an independent measurement of the sensitivity at 2·2 μ of a cell similar to the one used for the above tests gave a figure of 2×10^{-14} watt as the equivalent noise input (signal/R.M.S. noise) for a band width of 1 c./s. The area of the receiving surface was approximately 1 mm.^{2} and the time of response $1{\cdot}5 \times 10^{-4}$ sec.

High-Frequency Characteristics of Lead Sulphide and Lead Selenide Layers

RECENT work on the photoconductive effect in lead sulphide layers has suggested that the origin of both the high resistance and the photoconductive effect is in the intercrystalline barriers existing in such layers[1,5].

Impedance measurements have been made on lead sulphide and lead selenide photoconductive cells at frequencies high enough to ensure the substantial short-circuiting of these barriers. In all cases so far investigated, it has been found that as the frequency of measurement is increased the shunt resistance component of the cell impedance decreases until at about 60 Mc./s. a steady value is reached equal to a fraction of the D.C. value at room temperature. If the cell is cooled to the temperature of solid carbon dioxide (194·5° K.) or liquid oxygen (90° K.), the D.C. resistance increases exponentially in the usual manner found for semi-conductors, while the high-frequency resistance is only slightly affected. Either a small positive or a small negative temperature coefficient of high-frequency resistance is obtained, and the high-frequency behaviour is essentially semi-metallic.

For all the layers studied, the photoconductive effect decreased with increasing frequency, finally disappearing at frequencies high enough for the cell resistance to have reached a constant value.

These effects are illustrated in Figs. 1 and 2 for a lead sulphide cell which had been manufactured by a vacuum evaporation process.

Fig. 1 illustrates the variation of cell resistance with frequency at two temperatures, measurements being made with the cell illuminated and unilluminated.

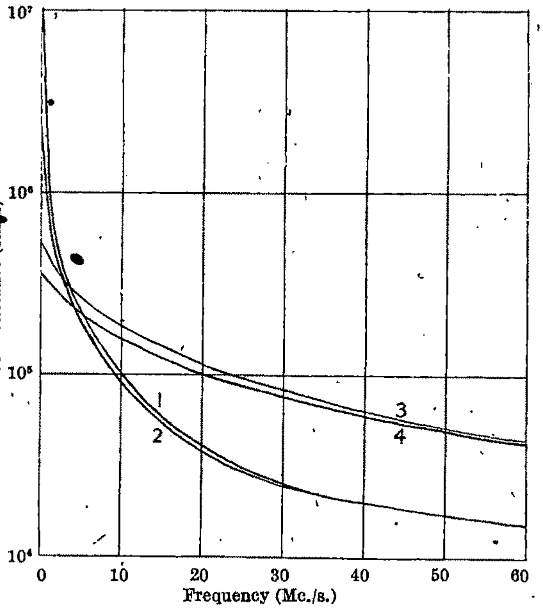

Fig. 1. Curves 1 and 2 ; 194·5° K., cell in darkness (1), illuminated (2).
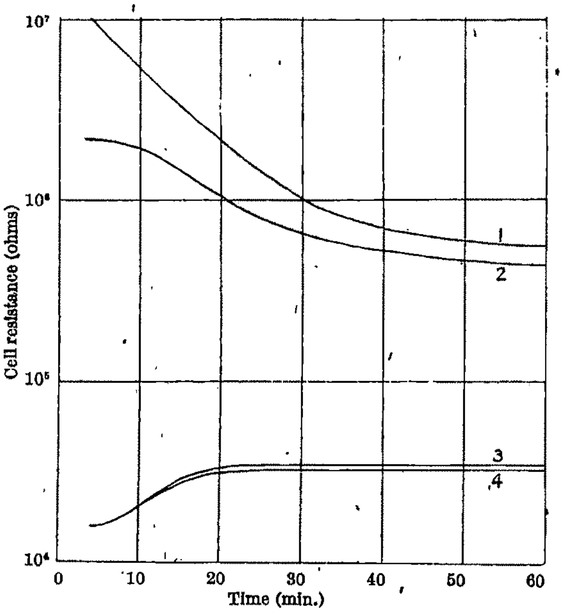
„ 3 „ 4 ; 297° K., „ „ „ (3), „ (4).

Fig. 2 gives an indication of the variation of cell resistance with temperature at low- and high-frequencies. The direct variation of cell resistance with temperature has not yet been determined at the high frequency, so it is hoped to make this the subject of a future experiment.

On the basis of the above results it would seem reasonable to draw the following conclusions :

(*a*) The presence of the photoconductive effect is associated with the intercrystalline barriers, as it disappears when these are short-circuited.

(*b*) The microcrystals constituting the photoconductive surface the impedance characteristics of which are measured at high frequencies are themselves semi-metallic in nature, thus indicating a high impurity content, resulting in energy-levels near the conduction band ; this fits in well with the measurements made by Dunaer[2] and Bauer[3] on single crystals.



CELL WARMING FROM 194·5° K. TO ROOM TEMPERATURE (297° K.)

Fig. 2. Curves 1 and 2 ; 1590 cycles, cell in darkness (1), illuminated (2).
„ 3 „ 4 ; 50 megacycles, „ „ (3), „ (4).

One apparent anomaly should be mentioned. Approximate values for the layer dimensions are length = 1 cm. ; width = 1 mm. ; thickness = 3×10^{-4} cm. Taking a high-frequency value for the resistance of 3×10^4 ohms, we find for the conductivity of the microcrystals a value of 0·01 ohm^{-1} cm.$^{-1}$ approximately.

This is of the order of a thousand times less than the usual values for impure semi-metallic single crystals[4]. Some explanation for this may perhaps lie in the fact that owing to the random size and shape of the microcrystals, the effective contact area of the crystals is considerably smaller than the size of the crystals themselves.

The above work was carried out in the laboratories of the Telecommunications Research Establishment (Ministry of Supply), and thanks are due to Mr. P. Handley (University of Oxford) and Mr. J. Newton (University of Cambridge), who assisted with the measurements described during their summer vacation.

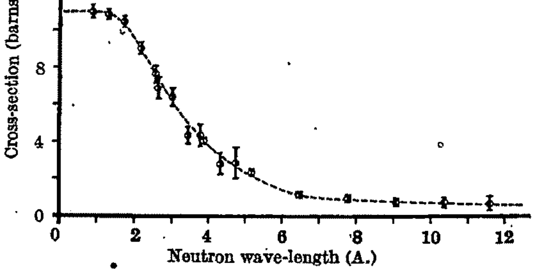
Scattering of Neutrons by Lead

THE University of Cambridge cyclotron and neutron velocity selector have been used for studying the scattering of neutrons by lead. The scattering cross-section as a function of the neutron energy was determined by measuring the number of neutrons scattered out of a collimated beam into a boron trifluoride counter placed near a cast lead scatterer. Neutrons scattered through angles between 30° and 150° (approximately) were counted.

The results show that the scattering cross-section, which is assumed to be 11 barns (1 barn = 10^{-24} cm.^{2}) at short neutron wave-lengths, drops to a value of 0·6 ± 0·3 barn at wave-lengths greater than about 6 A., owing to the microcrystalline structure of the lead.

No scattering should occur at long wave-lengths from an ideal lattice composed of identical coherent scattering centres. The observed residual scattering is the sum of contributions arising from thermal



vibrations, crystal defects, the presence of isotopes, and the different orientations of the nuclear spin. The experiment, therefore, fixes an upper limit to the residual scattering caused by the presence of several isotopes in lead:

$$s_{is} \leqslant 0{\cdot}6 \pm 0{\cdot}3 \text{ barn},$$

which does not disagree with the upper limits of 1·6 and 2·5 barns set by transmission measurements[1,2].

If we use the scattering length a as defined by Fermi[3], the normal random scattering cross-section is given by

$$\sigma = 4\pi \sum_r p_r a_r^2,$$

and the coherent scattering cross-section relevant in single crystal diffraction is

$$\mathbf{s} = 4\pi\Big(\sum_r p_r a_r\Big)^2.$$

The three cross-sections are related by the simple equation:

$$s_{is} = \sigma - \mathbf{s} = 4\pi(\overline{a^2} - a^2).$$

Since s_{is} is so small, it is evident that the minimum value of $\mathbf{s}$ is about 10 barns, and so the scattering lengths of all the major lead isotopes must be nearly equal. This is reasonable, since the small capture cross-section shows the absence of nearby resonances.

This result is in disagreement with the tentative value for $\mathbf{s}$ of 2·9 barns deduced by Fermi and Marshall[3] from measurements on a lead sulphide crystal. Substitution in their results of form factors modified in accordance with $\mathbf{s} = 10$ barns certainly gives an uneven decrease of intensity with order of reflexion, and it is not clear at present how this arises.

Production of Nitrogen Atoms in the Upper Atmosphere

EVIDENCE has accumulated in recent years that nitrogen is at least partially dissociated in the upper atmosphere. However, thus far the precise process causing the dissociation of nitrogen has not been established, except that it has been suggested that only the extremely short ultra-violet beyond 500 A. could produce it[1].

Recently, R. Herman[2], under certain conditions of discharge, found a breaking off above the level $v' = 6$ in the Lyman–Birge–Hopfield ($a-X$) bands of nitrogen. We have confirmed this breaking off in nitrogen excited at low pressure in a high-frequency electrodeless discharge. The appearance of our spectra leaves no doubt that we have here a predissociation of the N_2 molecule. The predissociation limit is between the levels $v' = 6$ and 7 of the $a\ {}^1\Pi_g$ state at an energy of approximately 9·8 eV., which agrees closely with the energy necessary to dissociate N_2 into $N({}^4S)$ and $N({}^2D)$, assuming $D(N_2) = 7{\cdot}38$ eV. The $a-X$ bands are the only absorption bands of N_2 above 1150 A. (see Birge and Hopfield[3]). The absorption is comparatively weak, since the bands represent a forbidden transition (see G. Herzberg[4]).

The $v'' = 0$ progression has been observed in absorption from the 0—0 to the 9—0 band. The 7—0, 8—0 and 9—0 bands have the wave-lengths 1249·3, 1226·6 and 1205·3 A. respectively. Absorption of solar radiation of these wave-lengths will lead to the production of nitrogen atoms in the upper atmosphere, since the molecules in the upper levels will undergo predissociation. The observation that in the laboratory the predissociation becomes noticeable only at low pressures indicates that the predissociation is a forbidden one. Nevertheless, in the upper atmosphere, a considerable fraction of the excited molecules will predissociate rather than return to the ground-state with emission of fluorescence.

On account of the comparatively low transition probability of the a—X bands, the formation of nitrogen atoms according to the above mechanism will go on over a very considerable range of heights, particularly since in the region 1150–1250 A. absorption by oxygen molecules is comparatively weak. It is thus possible to account both for the presence of nitrogen atoms at comparatively low heights and for the presence of nitrogen molecules at much greater heights (as observed in auroras).

While it is conceivable that nitrogen atoms may also be produced at much shorter wave-lengths through different mechanisms, we feel, in view of the much greater intensity of solar radiation at 1200 A. than at the shorter wave-lengths, that the mechanism here established is by far the predominant one.

The production of nitrogen atoms by predissociation in the a—X bands is independent of the correctness of the value of $D(N_2)$ assumed above. If one assumes Gaydon's value[5], the predissociation would lead to two normal atoms rather than one normal and one excited atom. However, it may be mentioned that the type of predissociation observed points strongly to the lower dissociation energy. Experiments are in preparation to settle this question definitely.

Calculation of the Piezo-electric Constants of α- and β-Quartz

α-QUARTZ possesses only two piezo-electric constants, ε_{11} and ε_{14}, given by the equations

$$\left.\begin{aligned} p_x &= \varepsilon_{11}(u_{xx} - u_{yy}) + \varepsilon_{14}u_{yz} \\ p_y &= -\varepsilon_{11}u_{xy} - \varepsilon_{14}u_{xz} \\ p_z &= 0 \end{aligned}\right\}, \qquad (1)$$

where p_x, p_y, p_z are the electric moments per unit volume developed on strain along the axes of the crystal, and u_{xx}, u_{xy}, etc., the components of strain. β-Quartz, which possesses a higher symmetry, has only one constant, ε_{14}, the other, ε_{11}, being zero. A method of deriving the above equations from the structure of the crystal, that is, the co-ordinates of the atoms in the unit cell, is not known. While the earlier work of Curie[1] (1882), Riecke[2] (1892) and Kelvin[3] (1893) is purely speculative, Gibbs[4] (1926) calculated the piezo-electric modulus δ_{11} on the basis of his structure and obtained a value which is nearly five times too high. Moreover, he did not calculate the other constant, δ_{14}, and did not show how the above equations can be obtained from his co-ordinates. We have been able to derive the above equations from the structure of Gibbs and have in this way obtained values of ε_{11} and ε_{14} which agree completely with the observed values. The piezo-electric constant ε_{14} of β-quartz and the variation of ε_{11} and ε_{14} with temperature in the case of α-quartz has also been calculated.

α-Quartz is a crystal with covalent bindings. The electric moment may therefore be supposed to arise from the displacements of the silicon and oxygen atoms in close neighbourhood. As each silicon is linked to four oxygens and each oxygen to two silicons, six Si—O bonds—there are twelve Si—O bonds in the unit cell—will correspond to a charge k_1e on each atom and the remaining six to a charge k_2e. In β-quartz, k_1 is equal to k_2, since all the bonds are equivalent.

It can be shown that in a general elastic deformation, the changes in the length of a line after strain, and the changes in the angles between two lines after strain, are completely given in terms of the strain components u_{xx}, u_{xy}, etc., and are independent of the rotation components ω_x, ω_y, ω_z (*vide* Love[5]). Any change Δr in the length of an Si—O bond would produce a moment $ke\Delta r$ in that direction, but the direction cosines of the line after strain are not known, since they involve the rotation components ω_x, ω_y, ω_z. We therefore take three points P, Q, R, such that P and R are silicon atoms and Q an oxygen atom, or *vice versa*, and resolve the electric moments due to the displacement of atoms in the plane of the Si—O bonds, PQR and perpendicular to this plane.

Since the components of strain u_{xx}, etc., are very small quantities, it is easy to show that the moments in the plane PQR may be regarded as produced by a change in the bond directions before strain, and the moment normal to the plane may be taken as half the value of the moment normal to the plane when the displacements of the atoms P, Q, R are entirely normal to the plane. This would be justifiable, since in an elastic deformation of the unit cell, the moments due to 36 O—Si—O planes and 6 Si—O—Si planes have to be considered.

If l, m, n are the direction cosines of Si—O bonds, and p, q, r of the normals to the various planes, we get in summing over all these planes:

$$p_x = \frac{e}{v}\left[\overset{\text{12 Si—O bonds}}{\Sigma}\, k\,.\,\Delta r\,.\,l\right] +$$

$$\frac{e}{8v}\left[\overset{\text{18 O—Si—O planes and 6 Si—O—Si planes}}{\Sigma}\left\{\frac{k_1+k_2}{2}\,(\Delta r_1 - \Delta r_2)\cot\alpha\; + \right.\right.$$

$$\left.\left.\frac{k_1-k_2}{2}\;\frac{r_3\,\Delta r_3 - r(\Delta r_1+\Delta r_2)\,(1-\cos.2\alpha)}{r\sin 2\alpha}\right\}p\right];$$

with similar expressions for p_y and p_z; here $PR = r_3$; Δr_1, Δr_2, Δr_3 are the variations of PQ, QR and PR; $r = PQ = QR$; $\angle PQR = 2\alpha$; $v =$ the volume of the unit cell.

These expressions resolve into equations (1) by giving p, q, r suitable signs. The calculation shows that the moments in the plane of the Si—O bonds (the first part of the above expression) make no contribution to the transverse coefficient ε_{14}. Assuming that the moments normal to the plane of the bonds give no contribution to the longitudinal coefficient ε_{11}, we find that if $\varepsilon_{11} = 5{\cdot}1 \times 10^4$ we get $k_1 = 0{\cdot}752$, $k_2 = 0{\cdot}695$, and $\varepsilon_{14} = 1{\cdot}23 \times 10^4$, in complete agreement of the observed values.

A similar calculation when applied to β-quartz gives $\varepsilon_{11} = 0$, and $\varepsilon_{14} = 1{\cdot}07 \times 10^4$ for a non-ionic crystal ($k = 0{\cdot}724$) and $1{\cdot}47 \times 10^4$ for an ionic crystal ($k = 1$). If the moments perpendicular to the plane of the bonds are supposed to give no contribution to the longitudinal coefficient, we find $k_1 = k_2$, which is the case in β-quartz. The assumption is therefore justified.

The variation of ε_{11} with temperature in α-quartz can be completely explained on the basis of change of co-ordinates with temperature. It is found that at 558° C. the silicon atoms in α-quartz occupy the same positions as they do in β-quartz. As the transition temperature is reached, the longitudinal coefficient in α-quartz drops to zero, but the transverse coefficient changes only by 12 per cent.

Max Planck

IN a broadcast talk on Max Planck, in which whole-hearted tribute was paid to his great work, I used the words, "If I hesitate to put Planck on a level with Newton and Einstein it must be partly on the ground that he did not seem to know quite what he had done when he did it . . . Planck seems to have been reluctant to realize the range of his innovation." I was, of course, basing my opinion upon his published work. I have just received a letter from Frau Planck, his widow, who has read the talk as printed in the *Listener* of November 6, 1947, p. 811, in which she says, "You have done justice to the scientist and to the man in every respect. I should only like to make one small exception. You think that he did not realize the scope of his discovery. Yet he did do so—though of course not in all its consequences. He said to our son with whom he had gone through a book on Galileo, Newton and Kepler, 'Look, my boy, I shall one day be in a book like this'. And to our other son he spoke as Sommerfeld has set it down." The reference is to an article of Prof. Sommerfeld's (*Die Neue Zeitung*, November 6, 1947), which I have received both from her and from Sommerfeld, where the following passage occurs: "Planck realized the scope of his discovery from the beginning. This is clear from an anecdote which Professor Bavinck, who died recently, repeated to me on the occasion of his lecture at Munich this year: he had it from his friend Erwin Planck, the son of the great man. The father said to the son in 1900, on the occasion of a walk in the Grünewald, 'Today I have made a discovery which is as important as Newton's discovery'."

Naturally both these conversations were unknown to me and do not affect the point that there is nothing in his writings to indicate this early realization of the importance of his discovery. They seem to be of sufficient general interest for the historian of science to warrant me laying them before the readers of *Nature*.

STONYHURST COLLEGE OBSERVATORY

THE closing of Stonyhurst Observatory on December 31, 1947, brings to an end more than a century of scientific work. Founded in 1838, the Observatory has been staffed and maintained by the Society of Jesus. Its first work was purely meteorological, and this has been continued throughout its existence. The Royal Society Commission, which in 1867 replaced the Board of Trade in the organisation of meteorological observations in Britain, selected Stonyhurst as one of the seven principal stations, each of which it supplied with standardized equipment and continuously recording instruments. For many years these stations formed the mainstay of British meteorology.

Stonyhurst Observatory was, however, early in its existence, to extend its activities to geophysics and astronomy. At the instance of Sir Edward Sabine, regular magnetic measurements were started by Perry in 1861, and continuous magnetic recordings a few years later. During the years 1868–70, Perry and Sidgreaves carried out an extensive magnetic survey of France and Belgium. In more recent years, seismology has also been included in the regular programme.

Astronomical work had already engaged the attention of Stonyhurst when the Observatory gave refuge to Secchi during the Italian troubles of 1848. Perry's interest in solar physics defined the direction which this work was to take. In 1881 he commenced the series of daily solar drawings, which were included in the routine of the Observatory for sixty years. To these drawings Sidgreaves and Cortie added the spectroscopic study of sunspots. In their pioneer research on the *B*—*D* region, which supplemented the work of Lockyer and Smart, they were among the first to detect molecular bands, and to identify the numerous vanadium and titanium lines. In addition, Cortie found time to use the material provided by the simultaneous solar and magnetic observations for an independent analysis of the interrelation of solar and geophysical phenomena.

During the years 1870–1914, the Stonyhurst astronomers played leading parts in a number of scientific expeditions, including both the transits of Venus (1874 and 1882), and seven solar eclipses. Astronomers will remember in particular the Royal Astronomical Society's eclipse expedition to French Guiana in 1889, which Father Perry led to a successful conclusion only at the cost of his life.

The considerable programme of solar and geophysical work and the relatively modest equipment of the Observatory made a continuous programme of stellar work impracticable. The occasional researches, mainly on the spectra of novæ, carried on within these limitations, were not for that reason desultory or ephemeral, but showed at times an eye for experimental technique of which a larger institution would not have felt ashamed. Stonyhurst was one of the few observatories to secure photographic spectra of Nova Aurigæ in 1892, the first nova to be so photographed. For this purpose Sidgreaves and Cortie used a slitless spectrograph with a collimated beam, instead of the objective prisms used at Harvard and at South Kensington. In this they anticipated Wadsworth's suggestion by a decade, and its common adoption by a still longer time. A similar ingenuity stamped the attempt to apply Orbinsky's length-of-spectrum method to the measurement, from objective-prism spectra, of the radial velocity of the expanding shell of Nova Aquilæ (1918). The astronomical work of Stonyhurst will always be associated with the name of Perry, but scarcely less credit is due to the originality of Sidgreaves, and the effective collaboration of O'Connor. While not so great an astronomer, Cortie contributed much to the spread of astronomical knowledge among a wider public.

The growing disparity between modern observational needs and the limited equipment of a private observatory has caused Stonyhurst in more recent times to return to the geophysical and meteorological work for which it was originally founded. This selfless task has been performed for many years by Father J. P. Rowland, the retiring director, whose advancing years and failing health have precipitated an inevitable though regretful decision. He will have the satisfaction of having completed a century of recording, and will terminate, temporarily at least, a line of priest-scientists whose solid achievement in their self-imposed task will be most readily admitted by their fellow physicists and astronomers.

P. J. TREANOR

THE ASSAYING OF PENICILLIN

THE first joint meeting of the Biological Methods and the Physical Methods Groups of the Society of Public Analysts and other Analytical Chemists, held on January 29 in the Barnes Hall of the Royal Society of Medicine, was devoted to methods of penicillin assay—their purpose, scope and validity. The plenitude of highly ingenious assay techniques in the chemical and physical and in the biological fields respectively were briefly surveyed by the opening speakers of the two sessions, Dr. E. Lester Smith and Dr. N. G. Heatley. A dozen or so specialized physical instruments have been pressed into service, several for more than one method, as have many more distinct chemical reactions and physical and microbiological techniques not involving instruments.

There were really two distinct problems under discussion, namely, the assay of *total* penicillin, and the assay of *individual* penicillins, at least five of which are now recognized as liable to be present in appreciable proportions in commercial penicillin supplies. It is perhaps clearer to adopt this division of the papers and discussions, rather than into non-biological and biological methods, as was done at the meeting.

Total penicillin may be assayed non-biologically with the aid of the polarograph, polarimeter, colorimeter (three methods), fluorimeter, ultra-violet spectrophotometer or Warburg manometer. Nevertheless, most of the people who do daily routine assays have simpler tastes and appear to favour the burette. Many of the other methods are now only of historical interest; the trouble with some of them is that they require more labour to carry them out than the biological methods they seek to replace, without offering adequate advantages by way of compensation. It is only fair to add that the biological methods have themselves been streamlined to cut down manipulation and improve accuracy, since some of these tests were invented in the early days of penicillin manufacture.

Two titration methods are available, each with minor variants. The first, the subject of a paper read by Miss S. J. Patterson, commends itself by extreme simplicity, being virtually a determination of saponification value. Dilute alkali quantitatively opens the β-lactam ring of penicillin in an hour or so at room temperature, whereupon the unused excess alkali is back-titrated to the cresol red end-point. The other, the iodometric method, involves somewhat more manipulation but is perhaps rather more specific; also, being much more sensitive, it is applicable, for example, to the assay of lozenges and other pharmaceutical products. It depends on the fact that the product of alkaline hydrolysis, penicilloic acid, is vigorously oxidized by iodine, consuming about eight atoms per molecule, whereas penicillin itself is not attacked: thus a blank determination, omitting only the hydrolysis step, corrects for oxidizable impurities.

The avowed object of the meeting was to discuss the "purpose, scope and validity" of the methods, and the speakers at the earlier session took this very seriously. Indeed, so frankly did they point out the limitations of their methods, that during the tea interval biologists could be heard proclaiming that their own methods remained virtually unchallenged. This, however, would be an unfair conclusion; despite the unavoidable uncertainty as to the proper factor for conversion to biological units, when assaying mixtures of penicillins, these non-biological methods have their place in routine control. They offer the advantages of speed and moderately high accuracy with a minimum of labour.

The biological methods have their shortcomings too, as we learned later; for example, when one speaker gave as an advantage of the turbidimetric over the plate diffusion methods, that it was less liable to break down completely and invalidate a whole day's assays. There are fundamentally three methods with innumerable variants. The earliest, the serial dilution method, appeared to engender depression among its devotees from the fact that the result is given by only one tube out of the six or more that must be set up for each test. Accordingly two speakers, Dr. C. G. Pope and Mr. C. R. Bond, described turbidimetric methods that appear to give greater æsthetic satisfaction as well as greater accuracy, from the fact that several tubes of the series are measured. The third group of methods, most widely used for routine control, are those depending on diffusion of penicillin from a hole in, or a cup, spot or disk of blotter upon, a sheet of agar seeded with a suitable organism, usually *B. subtilis* or *S. aureus*. A curious point was made by Dr. N. G. Heatley that merits some explanation: in the hole or cup techniques, the diameter of the ring of inhibition is controlled by the *concentration* of penicillin and not the total amount used, whereas in the spot or blotter-spot techniques, it is the *total amount* that matters irrespective of concentration. The Japanese, perhaps from a shortage of Petri dishes, apparently prefer vertical diffusion techniques, using test-tubes of seeded agar overlaid with the penicillin solution.

The biologists have the field almost entirely to themselves when it comes to assaying penicillin in body fluids. Some other methods will deal with penicillin solutions as dilute as these, but scarcely in the presence of so much interfering material, which indeed can cause errors in the biological methods too. The diffusion methods are not usually sensitive enough, unless an organism hypersensitive to penicillin is employed. Serial dilution methods are generally used, with micro tubes, capillaries or even single drops on microscopic slides.

Turning now to the determination of individual penicillins, this may be tackled by X-ray crystallography, or better by infra-red or ultra-violet spectrophotometry, as described by Dr. G. H. Twigg. The infra-red method, employing alanine or cystine as internal standard, exploits characteristic absorption bands for each penicillin species. At present it is limited to the examination of sodium salts in crystalline form, and accuracy is conditioned by the difficulty of preparing a uniform suspension of sample and standard in liquid paraffin. The other methods also have their snags and are mostly adapted to determine only one of the penicillins, usually benzylpenicillin (penicillin G or II). The few purely chemical methods have the same defect and were dismissed as of low accuracy. Much more satisfactory are the physical methods described by Dr. W. R. Boon, involving partition between buffer solutions and organic solvents, preferably ether. The very limited value of separating funnels may be enhanced by the counter-current apparatus of Craig. Complete separation of all the penicillins, however, demands chromatography on buffered silica columns or strips of filter paper, techniques developed by Dr. Boon's colleagues. He spoke of the difficulty of securing completely satisfactory separations on the silica columns (except of penicillin K), criticizing some American publications on the subject: another disadvantage is the destruction of 25 per cent or so of the input penicillin. The paper-strip method, on the other hand, can effect even the most difficult separations quantitatively under suitable conditions.

An interesting application of this technique is in checking the purity of penicillin standards. The International Standard, for example, was found to contain a few per cent of penicillins other than benzylpenicillin (G). Another application is in checking the specificity of a chemical method that has been adopted officially in the United States. It depends upon the precipitation of the crystalline salt of penicillin G with N-ethyl piperidine on adding this base to an amyl acetate extract of the penicillin, in presence of acetone. Dr. Boon stated that other penicillins are also precipitated from mixtures and that penicillin G is not obtained pure even on putting the precipitate through the process a second time. This lack of specificity was confirmed by Dr. Smith during the discussion: he had also found, using the same technique, that part of the penicillin G appears in the filtrate.

It was now the turn of the biologists to be discomfited, for their differential assay methods (using two organisms) came in for some pointed comments on account of their continued application to complex mixtures of penicillins, as well as to the binary mixtures for which they were designed. They retaliated by attempting to claim from the physicists the paper-strip microchromatographic method, on the ground that the penicillin zones are rendered visible by biological means (as zones of inhibition on seeded agar). It was, indeed, remarkable how unanimous the speakers were in praise of this method, although one wondered if this was not due more to despair of the other methods, and admiration for its originality and extreme elegance, than to any proof presented as to its accuracy. Its originators themselves admit that it is still in need of refinements and of a more precise check on its accuracy, using known mixtures of pure penicillins. Nevertheless it remains the only method capable of measuring all the penicillins simultaneously, yet simple enough for routine use.

Dr. Pope recorded the observation that nearly equal *weights* of penicillins G and K are adsorbed by suitable amounts of a washed charcoal; since the biological activities of these penicillins against *S. aureus* differ considerably, the amounts adsorbed *in units* also differ sufficiently to form the basis of an assay method. Like the differential assay methods, it is not applicable to more complex mixtures.

In vivo tests have been suggested for determination of heptylpenicillin (K) in mixtures, based on the observation that the protective value of this penicillin against experimental infections is much smaller than that of all the other common ones, namely, Δ^2 pentenylpenicillin (F or I), amylpenicillin (dihydro F), benzylpenicillin (G or II), and *p*-hydroxybenzylpenicillin (X or III). Such a test is naturally slow and expensive and of low accuracy. Its main value lies clearly in establishing the relative therapeutic efficacy of the penicillins rather than for assay of mixtures. Such work has recently produced some evidence for enhancing effects of one penicillin upon another, and also of two or three substances present in some crude penicillin supplies upon pure penicillins of all types.

Sir Alexander Fleming, opening the discussion after the second session, expressed his admiration for, and astonishment at, the galaxy of physical and chemical methods; but pointed out that the biological methods, though now more refined, were fundamentally those originally used in the discovery of the antibacterial activity of penicillin. Finally, Dr. A. A. Miles, director of biological standards at the National Institute for Medical Research, drew together and sorted the tangled threads of the discussion in a speech as witty as it was concise.

The full papers and discussion will be published in due course in the *Analyst* and also in booklet form.

LONG-DISTANCE CORRELATION OF BOULDER CLAYS

By D. F. W. BADEN-POWELL
University Museum, Oxford

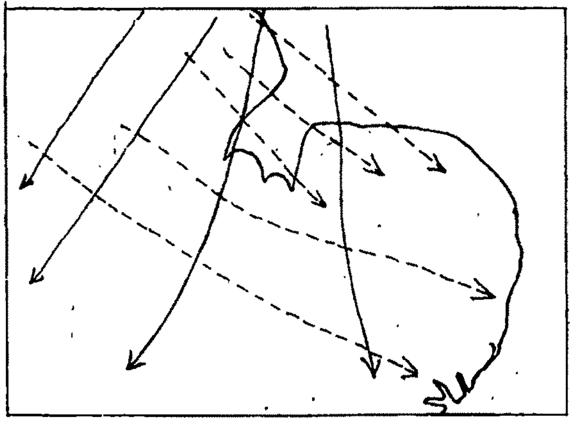
RESEARCH work on the glacial deposits of East Anglia during the last few decades has been directed mainly towards: (1) the establishment of a sequence of deposits; and (2) the discovery of the direction or directions in which the ice has travelled, as shown by the contents of the various beds. In order to combine these two lines of approach, I have recently undertaken a fresh examination of the glacial deposits, especially the boulder clays, and having determined some of the changes in ice-direction, have found that certain long-distance correlations which have been made, especially by Prof. P. G. H. Boswell, are strongly confirmed.

Knowledge of the glacial succession in East Anglia has accumulated very gradually, and the contributions of a number of geologists culminated in the sequence published in 1931 by Boswell[1]. Few alterations or additions have been made since that date, except in nomenclature, and the present state of our knowledge on the subject seems to be:

Youngest
  Hessle Boulder Clay (Brown Boulder Clay at Hunstanton).
  March Gravels (and probably the Brundon Gravels).
  Upper Chalky Boulder Clay (Solomon's 'Little Eastern')[2].
  Hoxne Interglacial.
  Lower Chalky Boulder Clay (Solomon's 'Great Eastern').
  Corton Beds (Wood's 'Middle Glacial')[3].
  Cromer Tills (included in 'North Sea Drift').
Oldest

Of the three boulder clays observed by Paterson[4] in the Breckland, the Upper Boulder Clay of that area is Boswell's Upper Chalky Boulder Clay, and the Middle and Lower Boulder Clays described by Paterson may be the equivalents of the Lower Chalky Boulder Clay and one of the Cromer Tills respectively, but further evidence is needed on this point.

Comparatively little work has been done on the direction of ice-movement as shown by the contents of the various boulder clays, although Harmer[5] showed that some of the material in the 'North Sea Drift' had come from a general northerly direction, whereas much of the content of the 'Great Chalky Boulder Clay' was obviously derived from the north-west, including Jurassic rocks from the Fenland. Harmer suggested that the ice-sheet responsible for that boulder clay fanned out from Fenland in several directions, eastward across Norfolk and Suffolk, southward towards London and westward up the valleys of the Great Ouse, Nene and Trent. The drifts carried during this fanning-out process are shown by symbols on the well-known map which accompanied his paper; but a detailed examination of this map shows that there are many contradictions to the 'fanning-out' theory, and in any case the exact date in Boswell's sequence at which this process took place is unknown.



DIRECTIONS OF ICE-MOVEMENT IN EASTERN ENGLAND. UPPER CHALKY BOULDER CLAY, →; LOWER CHALKY BOULDER CLAY, - - →

A fresh examination has therefore been made, especially of the chalky boulder clays of Suffolk, the results of which are now sufficiently advanced to prove that the Lower Chalky Boulder Clay of that area is the darker-coloured clay containing much Jurassic material, whereas the Upper Chalky Boulder Clay is paler, and contains more chalk and igneous rocks, and has come from a more northerly direction, and to the eastward of the Lincolnshire Wolds. It is therefore the Lower Chalky Boulder Clay which Harmer described as bringing Jurassic material across the Fenland from west of the Lincolnshire Wolds. The directions of these two independent ice-sheets are indicated on the accompanying sketch. These conclusions are based on the assumption that the Upper Chalky has picked up more chalk than the Lower Chalky, because its direction of movement nearly coincided with the strike of the chalk, whereas that of the Lower Chalky corresponded more nearly with the dip of that formation, and therefore crossed a smaller area of its outcrop. The foregoing observation refers to the strike of the chalk in Norfolk and Suffolk, with a direction approximately from north to south between Hunstanton and Mildenhall, and continuing south-west by Newmarket towards Royston.

The intensely chalky boulder clay of the Cromer district[3], on the other hand, can belong to the Lower Chalky glaciation, because ice from the north-west in northern Norfolk would have passed along the strike of the Lincolnshire chalk.

Apart from the matrix of the boulder clays, these ice-directions are confirmed by such erratics as have been collected *in situ* in the boulder clays. The Lower Chalky at Claydon, near Ipswich, contained flint, hard chalk, Neocomian sandstone, Red 'Chalk' (very rare, and doubtfully *in situ*), Septaria, Kimmeridge Shale, Oolite (probably from Lincolnshire), *Gryphæa* cf. *incurva*, Bunter quartzites, blue limestones (? Carboniferous or Jurassic), ? Millstone Grit and non-porphyritic basalts (which may be from Derbyshire). At Bawsey, east of King's Lynn, collection included flint, hard chalk, Neocomian Sandstone, *Terebratula* cf. *rosenkranzi* and *Pavlovia* cf. *worthensis* (Portlandian), and possibly Bunter pebbles. The same boulder clay at Pakefield, near Lowestoft, yielded similar Cretaceous and Jurassic rocks, including *Ostrea dilatata, Ostrea delta* and *Pachyteuthis abbreviata*. The Lower Lias is probably represented by *Lima hermanni*. The Lowestoft boulder clay also contains Bunter quartzites, blue limestone (? Carboniferous), basalt and a small rounded pebble of schist. This last erratic is probably derived from the underlying Corton Beds. If the long list of Jurassic fossils from Ormsby St. Margaret, published in the Geological Survey Memoir (Yarmouth), is taken into account, the Lower Chalky Boulder Clay is seen to consist of Cretaceous, Jurassic, Trias and probably Carboniferous pebbles in a matrix of various Jurassic clays. No other igneous or metamorphic erratics were found *in situ*. This boulder clay appears to be the product of Pennine Ice, which has travelled south-east across mainly Jurassic outcrops.

The Upper Chalky Boulder Clay is consistently different. Cretaceous material is much more common than Jurassic. Red 'Chalk' is abundant, especially at Claydon and Bolton's pits near Ipswich, also blue-and-white flint with the so-called 'basket-work' patina, which is not known to occur in the Lower Chalky. The Upper Chalky also contains Bunter pebbles, porphyrites of supposed Old Red Sandstone type, ? volcanic tuff, various felspathic grits and a sandstone with abundant tourmaline (at Hoxne). An erratic of rhomb-porphyry was found some years ago by Miss Tomlinson close to Upper Chalky Boulder Clay in Bolton's pit, Ipswich. Such Jurassic fossils as occur rarely could be derived from the Lower Chalky Boulder Clay. The Upper Chalky is therefore a deposit containing much flint, and erratics from apparent Scottish Old Red Sandstone, with others which could be derived from one of the Cromer Tills, in a matrix of sand and soft chalk. It appears to represent Scottish Ice, which has entered west Norfolk and Suffolk from a northerly direction off the existing Lincolnshire coast.

These two boulder clays are not often seen in direct superposition, but they are exposed together in the pit at Claydon, and have been seen in former sections at Hoxne and Derby Road brickworks at Ipswich (where the Upper Chalky is decalcified), at Bolton's pit, and probably elsewhere. Most of the Acheulean and associated implements of the Ipswich district come from interglacial deposits between these two boulder clays.

The marine March Gravels of the Fenland have been described as resting on a chalky boulder clay[6], and it is obviously not possible that the chalky boulder clay at Peterborough, for example, was laid down by ice crossing the oolitic rocks from the north-west. The chalky boulder clay of Fenland contains Cretaceous material from Lincolnshire, local Jurassic septaria, felspathic grit, and schists, and gneisses which could be derived from Cromer Till, in a matrix of local Jurassic clays. This assemblage, especially in southern and western Fenland, points to ice-movement from the north across the Lincolnshire Wolds. This direction is parallel to that of the Upper Chalky of West Suffolk, and the Fenland boulder clay is most easily accounted for as having been brought by the Upper Chalky Ice. It should be emphasized that it is different in many ways from the Hessle Boulder Clay of the Fens, which in any case overlies the March Gravels.

If this explanation of the chalky boulder clays is correct, correlation becomes possible between East Anglia and a large area of the East Midlands. Deeley[7], Boswell[1] and Hollingworth[8] have shown that the early Pennine Boulder Clay of the East Midlands underlies later chalky boulder clay from the north-east, and many of the relevant memoirs of the Geological Survey admit a similar sequence. The simplest explanation of these facts is that the older Pennine Ice from Derbyshire to the Fens was the same as that which deposited the Lower Chalky Boulder Clay of East Anglia: and that the younger ice which brought Cretaceous and other material from the north-east to the districts round the Trent, the Stratford Avon and the neighbourhood of Buckingham, was contemporaneous with that which deposited the Upper Chalky Boulder Clay of Suffolk. This hypothesis fits the facts better than Harmer's conception of a single ice-sheet with its fanning-out and cross-currents.

It is hoped to publish the full evidence on which this work is based as soon as possible. The boulder clay samples are still being worked out in detail. I would like to thank Dr. W. J. Arkell for identifying many of the Jurassic fossils.

AMALGAMATION OF SOME ALLOYS OF GOLD, SILVER AND COPPER

By Dr. DOUGLAS RENNIE HUDSON
University of Leeds

THE surface of amalgamated metals is greasy to touch, and lustrous in appearance like liquid mercury. In a previous publication[1] the extreme tenuity ($2 \cdot 7 \times 10^{-4}$ cm.) of the film necessary to confer these properties on a pure silver surface was noted. This observation has been confirmed for gold-rich alloys of the legalized carat compositions used for jewellery, for some silver alloys, and for bronzes. By the nature of the problem, exactly reproducible results could scarcely be expected, but, in fact, surprisingly concordant values have been obtained. The problem is of interest in the amalgamation of coarse gold concentrates from the corduroy table on the Rand[2].

Gold-rich alloys. Values of the equivalent film thickness in the hard-rolled state are too erratic to be compared, since in this condition the alloys crumble on mere contact with liquid mercury. This is the phenomenon of 'season cracking' attributed to intercrystalline penetration of the strained metal by liquid mercury.

In the rolled state (half-hard, with 'close' surface texture), the equivalent thickness of mercury is a little more than 1×10^{-4} cm. On fully annealing the gold alloys in hydrogen, giving a surface with 'open' texture, this thickness rises somewhat, attaining a value less than 2×10^{-4} cm.

After polishing the half-hard alloys to a 000 emery finish, the equivalent thickness is reduced to about a third. In annealed alloys similarly polished the equivalent thickness is very slightly less. The polishing appears to activate the surface and renders it very able to take up the mercury; a similar procedure may be adopted to bring annealed metals into a state of standard strain for electrode potential determinations.

Comparison tests on a few commercial golds showed a wide variation in the thickness of the equivalent layer, namely, $0{\cdot}45$–$2{\cdot}7 \times 10^{-4}$ cm. This is attributed to wide differences in the surface texture, polish, roughness and hardness. (A smooth surface may have an 'open' texture[3].) In all cases burnished surfaces yielded thin films. 18-ct. 'white gold' was particularly difficult to amalgamate. 'Rolled' gold gave the low value of $0{\cdot}22 \times 10^{-4}$.

Silver alloys. In silver alloys the effect of surface roughness is shown by the equivalent thickness of more than 3×10^{-4} cm. on the plated pure silver surface of a new shilling, compared with $2{\cdot}7 \times 10^{-4}$ cm. for pure silver and $0{\cdot}6 \times 10^{-4}$ cm. for the underlying basis metal containing only 50 per cent silver, when polished to a 000 emery finish. A similarly prepared surface on sterling silver (92·5 per cent) gave $0{\cdot}6 \times 10^{-4}$ cm.

On standing for a few hours, the lustrous surface becomes mat. This is not due, as might be suggested, to diffusion of mercury atoms into the silver crystals, and subsequent fixation as a result of synthesis[4] of Ag_3Hg_4. This process is much slower, and may take weeks, whereas the lustre of the mat surface can be restored by gentle rubbing. Probably it is due to thixotropic setting within the surface layer of mercury[5].

Copper alloys. Most gold and silver alloys amalgamate readily on mere contact with mercury, and the wetted area extends quickly on gentle rubbing. But copper and its alloys are difficult to amalgamate by contact, even when surface cleanliness is not in question. Prolonged rubbing is necessary, and it is not surprising that resulting films are much thicker, as much as 14×10^{-4} cm. having been observed. However, they do not seem to differ in behaviour from amalgamated alloys of gold and silver. This difficulty in wetting is quite consistent with immediate formation in air of a thin invisible oxide film on newly polished copper surfaces, which has been deduced from electron diffraction and surface reflectivity measurements. Chemical amalgamation yields much thinner films; about $1{\cdot}4 \times 10^{-4}$ cm. by displacement in mercurous nitrate solution, and about half that thickness in a mixture of mercury and nitric acid. This also is consistent with the shielding effect of an oxide layer.

Phosphor bronze, and copper alloyed with a little beryllium (so-called *beryllium bronze*) closely resembling it in physical properties, both gave surprisingly low thickness for contact amalgamation of surfaces polished to a 000 emery finish, respectively 0·07 and $0{\cdot}1 \times 10^{-4}$ cm. Values obtained by chemical amalgamation, while still small at $0{\cdot}12$–$0{\cdot}19 \times 10^{-4}$ cm. and $0{\cdot}35$–$1{\cdot}6 \times 10^{-4}$ cm., much exceeded the contact values. It is clear that surface conditions are very important in the amalgamation of copper alloys.

Grateful acknowledgment is made to the Carnegie Trust, which supplied the precious metals, and particularly to its secretary, Dr. Peddie.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, February 23

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Discussion on "Corrosion in Electrical Apparatus" (to be opened by Brigadier F. H. Maclennan).

INSTITUTION OF THE RUBBER INDUSTRY, MANCHESTER SECTION (at the Engineers' Club, Albert Square, Manchester), at 6.15 p.m.—Mr. L. A. Oliver: "Machinery and Layout in German Rubber Plants".

Tuesday, February 24

UNIVERSITY COLLEGE LONDON (in the Anatomy Theatre, Gower Street, London, W.C.1), at 1.15 p.m.—Prof. Daryll Forde: "Anthropological Analysis of Social Change".*

ILLUMINATING ENGINEERING SOCIETY (at the Lighting Service Bureau, 2 Savoy Hill, London, W.C.2), at 6 p.m.—Discussion "That Artificial Lighting is an Adequate Substitute for Natural Lighting".

SOCIETY OF INSTRUMENT TECHNOLOGY (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 6.30 p.m.—Dr. H. W. Thompson, F.R.S.: "Infra-Red Methods of Analysis and Control".

TEXTILE INSTITUTE (joint meeting with the MANCHESTER GEOGRAPHICAL SOCIETY, in the Geographical Hall, St. Mary's Parsonage, Manchester), at 6.30 p.m.—Mr. F. Shuttleworth: "Some Strange Native Customs and Ways of Using Textile Materials".

CHEMICAL SOCIETY, SOCIETY OF CHEMICAL INDUSTRY, and ROYAL INSTITUTE OF CHEMISTRY, EDINBURGH AND EAST OF SCOTLAND SECTIONS (joint meeting with the EDINBURGH UNIVERSITY CHEMICAL SOCIETY, in the Biochemistry Lecture Theatre, Teviot Place, Edinburgh), at 7 p.m.—Prof. W. F. K. Wynne Jones: "Proton Transfer and Analogous Reactions".

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON STUDENTS' SECTION (at Savoy Place, Victoria Embankment, London, W.C.2), at 7 p.m.—Mr. P. Good: "The General Aspects of Standardization" (Presidential Address).

SOCIETY OF DYERS AND COLOURISTS, SCOTTISH SECTION (at St. Enoch Hotel, Glasgow), at 7 p.m.—Mr. E. Marney: "All-over Pigment Coloration of Textiles".

ROYAL INSTITUTE OF CHEMISTRY, LONDON AND SOUTH-EASTERN COUNTIES SECTION (at the Cherry Tree, Welwyn Garden City), at 8 p.m.—Prof. D. H. Hey: "Reactions of Benzoyl Peroxide".

Wednesday, February 25

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Mr. C. Butement: "Three-Dimensional Photography".

ROYAL MICROSCOPICAL SOCIETY, SECTION OF INDUSTRIAL MICROSCOPY (in the Hastings Hall, B.M.A. House, Tavistock Square, London, W.C.1), at 5.30 p.m.—Miss M. Dempsey: "The Structure of the Skin and Leather Manufacture".

SOCIETY FOR VISITING SCIENTISTS (at 5 Old Burlington Street, London, W.1), at 7.30 p.m.—Discussion on "The Growing Points in Science", 2. (To be opened by Prof. A. A. Hall and Prof. C. H. Waddington, F.R.S.)

Thursday, February 26

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Sir Wallace Akers: "The Research Laboratories of the Imperial Chemical Industries, Ltd.".

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Exhibition Meeting (Exhibits of botanical and zoological interest, with brief comments by the Exhibitors).

Royal Aeronautical Society (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 6 p.m.—Prof. R. L. Lockley: "The Evolution of the Design of an Aeroplane".

Royal Statistical Society, Sheffield Group of the Industrial Applications Section (at the Royal Victoria Hotel, Sheffield), at 6.30 p.m.—Miss B. Pickersgill: "Graphical Methods for the Demonstration of Simple Statistical Relations".

Royal Institute of Chemistry, Manchester and District Section (at the Engineers' Club, Albert Square, Manchester), at 7 p.m.—Mr. J. H. Carrington: "Rubber".

Royal Photographic Society, Scientific and Technical Group (at 16 Prince's Gate, London, S.W.7), at 7 p.m.—Annual General Meeting, followed by a Film Show.

Society of Dyers and Colourists, West Riding Section (at the Great Northern Victoria Hotel, Bradford), at 7.15 p.m.—Dr. A. H. Gordon: "The Composition of Wool".

Friday, February 27

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Geophysical Discussion on "Recent Work on the Earth's Main Magnetic Field". (Fellows of the Geological Society are invited to attend.)

Institution of Mechanical Engineers (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Discussion on "The Future of Fuel and Power" (to be opened by Dr. F. Rogers).

British Institution of Radio Engineers, Midland Section (at the Technical College, The Butts, Coventry), at 6.30 p.m.—Mr. G. F. N. Knewstub: "The Design of Electronic Calculating Machines".

Institution of Electrical Engineers (at the Central Hall, Westminster, London, S.W.1), at 6.30 p.m.—Dr. P. Dunsheath: "Electricity and Everyman" (Faraday Lecture).*

British Glaciological Society (at the Electrical Laboratory, Oxford), at 8.15 p.m.—Mr. Gerald Seligman: "Some Aspects of Snow and Glaciers".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. Linus C. Pauling: "The Nature of Forces between Large Molecules of Biological Interest".

Universities Federation for Animal Welfare, Cambridge University Branch (at St. John's College, Cambridge).—Symposium on "Pain" (to be opened by Prof. E. D. Adrian, O.M., F.R.S., and Sir Frederic Bartlett, F.R.S.).*

Saturday, February 28

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Dr. Redcliffe N. Salaman, F.R.S.: "The Potato Came to Europe".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Plant Pathologist to investigate an unexplained disease of coconuts, in Jamaica—The Under-Secretary of State, Colonial Office (Research Department), Palace Chambers, Bridge Street, London, S.W.1 (February 28).

Laboratory Steward at the College, Swindon—The Borough Education Officer, Civic Offices, Swindon (February 28).

Chemists (men and women), Scientific Officer Class and Experimental Officer Class, in the Chemical Inspection Department of the Ministry of Supply—The Ministry of Labour and National Service, Technical and Scientific Register, Room 669, York House, Kingsway, London, W.C.2, quoting F78/48A (February 28).

George William Britt Studentship in Physics, and the Arthur Jubber Studentship for advanced study or research in any subject, preferably in the field of Chemistry, Botany, Mathematics, Ancient, Modern or Natural History—The Academic Registrar, University of London, Senate House, London, W.C.1 (March 1).

Graduate Assistant (with zoology degree and good field knowledge of birds)—The Director, Edward Grey Institute, 91 Banbury Road, Oxford (March 5).

Senior Assistant in the Electrical Engineering Department—The Principal, Northampton Polytechnic, St. John Street, London, E.C.1 (March 6).

Principal Scientific Officer at the Post Office Engineering Research Station, Dollis Hill, London, N.W.2, to advise and undertake research work on physiological problems—The Director General, Personnel Department (C.C.B.), Headquarters Building, General Post Office, London, E.C.1 (March 8).

Science Master at Longerenong Agricultural College under the Victoria Department of Agriculture—The Secretary, Universities Bureau of the British Empire, 8 Park Street, London, W.1 (March 8).

Geologists (about 10) and Senior Geologists (1 or 2) at the Geological Survey and Museum—The Secretary, Civil Service Commission, Scientific Branch, 27 Grosvenor Square, London, W.1, quoting No. 2117 (March 15).

Professor of Psychiatry—The Registrar, The University, Leeds 2 (March 22).

Senior Lecturer and Lecturers (2) in Physiology—The Secretary of University Court, The University, Glasgow (March 31).

Principal Scientific Officer for work on the Commonwealth Potato Collection, Cambridge—The Secretary, Commonwealth Agricultural Bureaux, 2 Queen Anne's Gate Buildings, London, S.W.1 (April 1).

Assistant in Astronomy—The Director, University of London Observatory, Mill Hill Park, London, N.W.7 (April 1).

Ramsay Memorial Fellowships for Chemical Research—The Joint Honorary Secretaries, Ramsay Memorial Fellowships Trust, University College London, Gower Street, London, W.C.1 (April 17).

Principal Meteorologist, a Senior Meteorologist, a Meteorologist and a Junior Meteorologist; a Principal Technical Assistant, a Senior Technical Assistant, and a Technical Assistant (Grade I), in the Meteorological Services, Department of Transport, under the Government of the Union of South Africa—The Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, London, W.C.2 (April 30).

Chair of Pharmacology—The Registrar, The University, Sydney, N.S.W., Australia (June 30).

Lecturer in the Chemistry Department—The Secretary, King's College of Household and Social Science, Campden Hill Road, London, W.8.

Laboratory Assistant (girl or woman)—The Principal, Furzedown Training College, Welham Road, London, S.W.17.

Laboratory Assistant (woman) at Dalston County Secondary School, Shacklewell Lane, London, E.8—The Education Officer (Estab./2), County Hall, London, S.E.1.

Laboratory Steward (Grade C)—The House Governor and Secretary, Gordon Hospital, Vauxhall Bridge Road, London, S.W.1.

Organizing Secretary of the proposed Institute of Education—The Registrar, University College, Leicester.

Science Graduate (Senior Scientific Officer grade) with an interest in economics and statistics to carry out operational research in the iron and steel industry—The Personnel Officer, British Iron and Steel Research Association, 11 Park Street, London, W.1.

Demonstrator for the Department of Aerodynamics—The Registrar, College of Aeronautics, Cranfield, Bletchley, Bucks.

Assistant Technical Librarian—The Secretary, British Internal Combustion Engine Research Association, 111–112 Buckingham Avenue, Slough, Bucks.

Histological Technician (Grade B) in the Department of Anatomy—The Secretary, St. Mary's Hospital Medical School, Paddington, London, W.2.

Government Chemist in Mauritius—The Director of Recruitment, Colonial Service, 15 Victoria Street, London, S.W.1.

INTERNATIONAL CONTROL OF ATOMIC ENERGY

THE sober, and somewhat sombre, review of the proposals for the international control of atomic energy, and the appraisal of the present position, which Dr. J. R. Oppenheimer, chairman of the Advisory Committee of the Atomic Energy Commission of the United States, contributes to the current issue of *Foreign Affairs*, appeared appropriately just when President Truman's Air Policy Commission had warned the United States that within five years foreign countries would almost certainly possess atomic weapons in quantity and would probably also have in mass production effective long-range guided missiles. Dr. Oppenheimer's review should receive close study, not merely by those directly interested, but also by scientific workers generally, on its own intrinsic merits. Apart from Dr. Oppenheimer's authority, it is a most valuable indication of the trend of opinion which has led to the specific recommendations of the Air Policy Commission, and as such assists materially in appraising their significance.

Dr. Oppenheimer attempts to present, briefly but objectively, some of the sources of United States policy, and the formulation of that policy in the context of contemporary events. His article is also useful in assisting those outside the United States to estimate not merely the sound and durable elements in that policy, but also the reasons for its present lack of success. He does not enter deeply into political considerations, though they are not ignored; but the scientific and technical aspects are presented in balance with the political aspects in a way that should facilitate realistic discussion.

Early in this article, Dr. Oppenheimer makes the important point that the advantages which could come from the exploitation of atomic energy do not appear to be of such a character that they are likely to make a short-term contribution to the economic or technical well-being of mankind. It was clear two years ago that, although the generation of useful power from atomic sources was possible and that decisive progress in favourable circumstances was probable within a decade, the question of the utility of this power, the scale on which it could be made available, and the costs and general economic values would take a long time to answer. Intensive development and exploration are required; no evaluation, in Dr. Oppenheimer's view, could justify regarding atomic power as likely to provide immediate economic aid on a world-wide scale, or give its development the urgency of the control of atomic armaments. Similarly, he reminds us that the other form of application, involving the use of tracer materials, radioactive species, and radiations for science, the practical arts, technology and medicine, depends in the first instance upon the skilful development of chemical, physical and biological techniques—a development which under the best conditions is a gradual and continuing one.

It follows from this that the development of atomic energy for such peaceful purposes cannot present a direct appeal to the weary, hungry, almost desperate peoples of a war-ravaged world. Despite its challenge to the interests of technical men, and also to the vision of the statesmen concerned with long-term projects for human welfare, honesty compels us to regard such development as falling within the category of long-term projects, the development and exploration of which may have to be deferred until immediate needs have been met. That view lends some support to proposals which have already been advanced elsewhere, for example, by Mr. Lewis Mumford in "Programme for Survival", that we should forgo the use of atomic power until the world is better prepared for it.

Even if it is clear that mankind would lose little in the next few decades by such renunciation, it still remains to be seen whether it is practicable, even if it is wise, to postpone consideration of the control of large-scale power production. Here it should be noted, as Dr. Oppenheimer reminds us, that the development of atomic power cannot be separated from the technological development essential and largely sufficient for the manufacture of atomic weapons; and again, neither the development of power nor the effective and widespread use of the new tools of research and technology can prosper fully without a degree of freedom in regard to the technical realities difficult to reconcile with the traditional requirements of military security about the development of weapons of war.

These views have been overshadowed in most discussions by preoccupation with the control of atomic energy to the extent required to prevent its use for destructive purposes, and more especially with those considerations which derive from the nature of atomic armament. The main concern of the latter part of Dr. Oppenheimer's paper is to redress the balance, and to give to those arguments derived from the political climate of the post-war world the preponderance in determining policy which he considers they should have. Indeed, he contends that our excessive concern with the arguments based on the nature of atomic armament are the main cause of estrangement and misunderstanding with the U.S.S.R., and that relegation of problems of atomic energy to discussions with the United Nations has prejudiced the chances of any genuine international intellectual co-operation.

Dr. Oppenheimer recognizes fairly enough that during the Second World War the fabric of civilized life was worn so thin in Europe that there is the gravest danger that it will not hold. He admits, too, that the question of the future of atomic energy presents itself in one main constructive context: What can be done with this development to make it an instrument for the preservation of peace and for bringing about those altered relations between the sovereign nations, on the basis of which there is some reason to hope that peace can be preserved? He argues, however, that although this may have been the question in principle, a far more concrete and immediate problem faces the world, namely, whether the co-operative control and development of atomic energy might not play a unique and decisive part in establishing co-operation between the U.S.S.R. and the United States.

For all its frustrations and disappointments, the Atomic Energy Commission of the United Nations, notwithstanding the limitations under which it has worked, has proved the vitality of the basic idea of security through international co-operation. Dr. Oppenheimer does not examine the question whether the United States, Great Britain, Canada, and those other nations that are prepared to accept the necessary sacrifice of national sovereignty involved in a control system with its essential international inspectorate, should go ahead and demonstrate in a limited field the feasibility of such a scheme. He rightly observes that collaboration in the field of atomic energy cannot be entirely separated from collaboration in other fields; and although he does not suggest that it would necessarily have succeeded, he argues that an attempt should have been made to influence the U.S.S.R. at a higher level and to make the heads of the Soviet Union, in part at least, party to the effort at control.

That effort has not been made, and only the historian can pronounce upon the probability of its success. Meanwhile, we have to face the fact that the most unexceptional formulation of principles set forth in the report "International Control of Atomic Energy: Growth of a Policy" (Washington: Department of State Publications, 2702; 1947) confronts the evasion of the very bases for co-operation between the United States and the Soviet Union. Episode after episode in the last two years has emphasized their deep conflicts of interest, the apparently mutual repugnance of their ways of life, the non-co-operativeness of the Soviet Union and its apparent conviction of the inevitability both of the decay of American democracy and of conflict.

In such an atmosphere there can be little hope that measures of international control less radical than those already proposed by the United States will be either adequate or acceptable. Even in a situation less tense, there would have been considerable difficulties in reconciling particular national security, custom and advantage with an overall international scheme for security. In the present juncture, formal renunciation of atomic armament and some concession with regard to access to atomic facilities on the part of international inspectors is no more likely to commend itself as adequate to Great Britain and other nations than to the United States or Canada. Dr. Oppenheimer himself sees little hope except in a profound change in the whole orientation of Soviet policy, and a corresponding reorientation of American policy, even in matters far from atomic energy; though he urges that those who work for the establishment of peace and who wish to see atomic energy contribute whatever is possible to that end should maintain all that is sound in the early hopes and work for their eventual realization.

One road to peace may be through a limited scheme of control applying to the Western democracies. This may give time for the creation by writers, artists, scientific workers, teachers, and travellers of a widening field in which there is a common human bond and understanding between the diverse peoples of the world.

In this connexion the discussions now proceeding on an international declaration on human rights may be of significance. The British delegation, for example, is in favour of a covenant containing legally enforceable obligations, and in the Foreign Office draft Bill of Human Rights the obligations deemed acceptable are limited to those guaranteeing the existing common law rights of Englishmen. The accompanying memorandum argues that the right of all persons to work, to education, to social security and similar social and economic rights cannot "by their nature" be defined in the form of legal obligations for States. It is, however, precisely these obligations which the Slav bloc might conceivably accept as, in its view the indispensable guarantees of true political freedom. Without suggesting that the cause of peace will be furthered by any slackening of the effort to spread Western ideals of political freedom, it may well be, as Mr. Bryan King suggests in *The Economist*, that an international treaty is not the right medium for their propagation; such an instrument should afford rather the opportunity to establish or affirm common aims which will help to dispel mistrust and open the way to better understanding. Whatever views may be held as to the practicability or value of an international affirmation of faith in fundamental human rights and in the dignity and value of the human person, there can be no question as to the importance of not allowing either an idealistic or a legalistic point of view to accentuate differences and place fresh obstacles in the way of international understanding.

In this context it may be recalled that the Atomic Scientists' Association, although limiting its full membership to scientific workers with specialist knowledge of atomic energy, seeks to enrol the support of a large body of associate members, both scientific and lay, to broaden the activities and to increase the effectiveness of the Association. Such support is clearly invaluable and indeed essential for the expansion of the publicity activities of the Association. It should also counteract any tendency to approach the problems of atomic energy from too narrow an angle, and help to bring those intimately concerned with atomic physics into closer touch with other men of science, and the ordinary citizens alive to the larger issues at stake.

The report of the Air Policy Commission of President Truman provides a first-rate example of how much depends on the existence of an informed body of responsible opinion. The specific recommendations of the report are indeed less important than the affirmation by this body of distinguished private citizens of their belief that "the United States will be secure in an absolute sense only if the institution of war itself is abolished under a regime of law. World peace and the security of the United States are now the same thing." Even the most optimistic view of the record of the United Nations affords no assurance that that Organisation will develop in time the necessary authority to prevent another war.

It will be noted that this blunt report and the hardening of opinion which it tokens has something in common with Dr. Oppenheimer's conclusions and with the trend of thought elsewhere. There can now be little to hope from another examination of the current Russian proposals, and the Atomic Energy Commission has held only one ineffective meeting since its second report was made to the Security Council in September. The question of atomic energy and its control and development is now merging into the larger issues of which it forms a part; and when the Air Policy Commission expresses its belief that a strong America will be a force for peace, it is giving expression to views which are widely held and responsibly endorsed among the Western democracies. But the nations joining in any limited scheme of collective security, including the control of atomic energy as one essential element, must make clear what they regard as essential interests and make known resolutely and unambiguously where they will make a stand; and at the same time, they must use every means available to promote understanding and good will, and to demonstrate afresh the inherent greatness and resilience of Western civilization and its tradition and heritage of human individuality and freedom. Demonstration of the moral, spiritual and economic strength of Western Europe may in due course prepare the way for the adherence of the U.S.S.R. to a system of collective security the practicability and soundness of which has been made evident.

CONTROLLING THE STAFF OF LIFE

Modern Cereal Chemistry

By Dr. D. W. Kent-Jones and Dr. A. J. Amos. Fourth edition. Pp. vii + 651. (Liverpool: Northern Publishing Co., Ltd., 1947.) 50*s*. net.

IT were a work of sheer supererogation to recommend "Kent-Jones and Amos" to cereal chemists or to any of those concerned with the technical side of the milling and baking industries. They will all have this new (fourth) edition, if not on their shelves then certainly on order—or on loan! Indeed, there is much to be said for the definition of cereal chemist as "a graduate in chemistry whose work makes it essential for him to possess Kent-Jones and Amos and to consult it at least once a day!" To avoid gilding the lily or piling Pelion on Ossa or whatever may be the appropriate metaphor, I propose as a non-cereal chemist to consider in this review how far "Modern Cereal Chemistry" may be of value as a permanent companion of chemists practising in other branches of the food and allied industries. To do this it will be simplest to take a look at each chapter or group of chapters separately.

We begin, then, by considering the "Composition of Wheat and Products of Milling", which contains photographs of two delightful pieces of Egyptian statuary, dated 3300 B.C. The authors' subject has indeed a history. Not only have we in this chapter a detailed discussion of the proximate analysis of wheat and its milling fractions, but the chemistry of the carbohydrate, protein and fat constituents is also exhaustively expounded. A chapter like this should be of value and interest to any chemist who has ever to handle wheat or its milling products, even if only as a direct consumer of the grain or an indirect consumer of its milling products by way of the domestic hen's eggs. It is worth noting that neither in this chapter nor in any part of this book do the authors for a moment connive at that distressing term 'wheat berry', which has somehow crept into scientific jargon and is curiously difficult to exorcise. The wheat grain, as they point out on page 1, is a seed.

Chapter 2, on "Principal Wheats of the World", has an obvious interest for botanist and geneticist; it is also aimed at the pestologist, for it contains descriptions of all the leading wheat diseases due to infection or infestation and to methods of getting rid of them. Chapter 3, on "Barley", includes consideration of malt, but maintains a discreet silence on the main technological problem connected with the use of malted barley, for reasons, no doubt, of space rather than of personal predilection. Brewing has, in any event, many excellent text-books of its own already. Chapter 4 gives in admirably condensed form summarized data about four more cereals—rye, oats, maize and rice—as well as about two non-cereal sources of carbohydrate of world-wide importance—soya and the potato. Chapters 3 and 4 must obviously be immediately accessible to any chemist who has frequently or regularly to handle any of these food plants or their products, whether they be destined for human consumption, for stock-feeding or for industrial exploitation.

The next three chapters bring us directly into the field of milling technology and deal respectively with "Some Physico-Chemical Aspects of Flour", "Flour Strength" and "Conditioning and the Effect of Heat on Wheat and Flour". They may well be considered along with certain later chapters—"The Technique and the Chemistry of the Baking Process" (9), "Bleaching and Flour Improvers" (10) and perhaps also "Dough Testing Apparatus" (11). It is interesting to those who maintain the impossibility of separating 'pure' and 'applied' science to note how many problems in fundamental biochemistry crop up during the discussion of such mundane matters as the baking qualities of flour, which leads to a condensed but admirable general exposition of *p*H and *r*H, with incidental references to the electronic theory of atomic structure. The intensity of research effort that has gone into many of the basic phenomena underlying industrial practice is well exemplified by a passage in Chapter 10 where the authors, discussing the action of flour improvers, refer to the work of Jørgensen on the use of potassium bromate. On this extremely specialized problem the Danish worker has produced a volume of 434 pages—with a bibliography of no less than 10 pages and 218 references[*]. Kent-Jones and Amos write of this book that the author "has certainly put up a good case for his theory and has replied to a number of his critics". It would ill become a non-expert to add to this masterly comment.

Chapter 8, on the "Composition of Milled Products", is a logical extension of Chapter 1. It is packed with tabular matter and carries with it the conviction that nothing known about the chemical make-up of commercial wheat products has passed through the authors' fine-meshed bibliographic bolting-cloth. Many of the data included are based on their own work, which the bibliography (42 pages at the end of the book) shows to go back at least to 1924. "Use of Wheat and Flour for Special Purposes" (Chapter 12) covers such subjects as self-raising flour and baking powder, biscuit manufacture, confectionery, macaroni, dog biscuits and alcohol production.

Two of the longest chapters, as is only right, are those concerned with "Nutritive Value of Cereals" (12) and "Cereal and Balanced Rations for Livestock" (13). For certain obvious reasons I will not comment on these, except to say that the authors, though convinced supporters of a 'white bread' policy, preferably with enrichment, state the case of their opponents who favour the use of long-extraction flour with a fairness and objectivity that might well be an example to some of those opponents. These two chapters, depending as they do for their validity on accurate knowledge about the nutrient analysis of cereals and their products, extend the earlier chapters (1 and 8), and justify the meticulous details of the final two chapters on methods of analysis. These are "General Analytical Procedure for Cereals" (17) and "Assay of Vitamin Content of Cereals and Cereal Products". Here, surely, is the last word (at January 1947) on how to measure the individual compounds present in the most important of all man's foods.

There remains space only to mention the titles of Chapters 15 and 16, "The Microbiology of Cereals" and "Moisture in Cereals and Cereal Products", and thirty pages of tabular appendixes, giving figures on such diverse subjects as the atomic weights of the elements, relative humidities and compositions of ingredients used in common feeding stuffs. Could not future editions include a table of the manifold, and often mysterious, measures used in the milling and baking industries?

Finally there is, of course, a thoroughly adequate index (31 pages) to end a book for which, and for the knowledge, energy and enthusiasm that have gone to the writing and rewriting of it, there is only one word—prodigious! A. L. BACHARACH

SERVO-MECHANISM FUNDAMENTALS

Servo-mechanism Fundamentals

By Henri Lauer, Robert Lesnick and Leslie E. Matson. Pp. xi + 277. (New York and London: McGraw-Hill Book Co., Inc., 1947.) 17*s*. 6*d*.

THE use of the word 'fundamentals' in the title of this book is fully justified. A careful and detailed analysis of the physical principles underlying the operation of servo-mechanisms is made, with relation, in particular, to mechanisms for position control. The mathematical treatment is, in the main, on the transient basis—that is to say, the application of a 'step velocity' input—and deals in separate chapters with systems employing viscous output damping, error-rate damping, integral control and the various combinations of these features used in practice. It is noteworthy that the mathematical analysis is by straightforward classical methods very fully detailed, no recourse being made to operational methods or other specialized techniques. This is a valuable feature, for the presentation is, in consequence, well suited to the student with no greater mathematical background than that of the regular undergraduate course in science or engineering.

---

[*] Studies on the Nature of the Bromate Effect. By Dr. Holger Jørgensen. Pp. 435. (Copenhagen: Einar Munksgaard; London: Oxford University Press, 1945.) 40 Danish crowns; 40*s*.

While emphasis is placed rather on the characteristics and performance of systems of generalized type, attention is also given to the nature and behaviour of the various elements in the mechanism. Error-detecting devices are considered in a chapter devoted to 'follow-up links', and a further separate section deals with typical electrical networks employed in connexion with error-rate stabilization. Only brief attention is given, mainly in the final chapter, to the amplifier controller.

Along with the detailed solutions of the differential equations for step velocity input, which constitute the main body of the theory, is given a brief development of the solutions for sinusoidal input. This is extended in a chapter dealing with the transfer function analysis of servo-mechanisms. The correspondence with feed-back amplifier theory is demonstrated, and the application of the stability criterion to servo systems is briefly considered.

A particularly valuable feature of the book is the number of worked numerical examples incorporated in the text.

A very effective effort has been made by means of detailed descriptions and the use of mechanical analogies towards providing a clear physical picture of the main phenomena of servo systems. Rather less successful has been the attempt made in Chapter 3 to provide, in the same volume, a condensed account of the basic mechanics and electricity required for the study of servo systems. The space occupied by this restatement of the elements of mechanical and electrical theory might have been more usefully employed in dealing a little more fully with the amplifier-controller element of the servo-mechanism and introducing the fundamental concepts of the effects of 'noise' in amplifying systems.

This book provides, however, a most satisfactory introduction to the principles of servo-mechanisms.

THE LAURENTIAN HORMONE CONFERENCE

Recent Progress in Hormone Research

Proceedings of the Laurentian Hormone Conference. Vol. 1. Edited by Gregory Pincus. Pp. v+399. (New York: Academic Press, Inc.; London: H. K. Lewis and Co., Ltd., 1947.) 7.50 dollars.

THE Laurentian Hormone Conference had its origin at the 1943 meeting of the American Association for the Advancement of Science. The proceedings of the endocrinological section were so successful that the Montreal Physiological Society invited its participants to regather in Canada in 1944. A profitable reunion was held in the Laurentians, and the Laurentian Hormone Conference is now established as an annual event.

The present volume is a report of the 1945 meeting, and consists of four main sections, the first on neurohumoral relationships, the second on the chemistry and physiology of adrenal hormones, the third on the role of hormones in metabolic processes, and the fourth on aspects of clinical endocrinology. Each section comprises from two to four general papers, followed by a record of the subsequent discussions.

It is difficult to single out, from what is a collection of well-chosen and well-presented papers, any particular contribution for detailed mention. Beach's paper on "The Hormones and Mating Behaviour in Vertebrates" is undoubtedly the best review that has yet appeared on the subject. The conclusions he draws from the available information are: (1) that some hormones affect sexual behaviour by virtue of their control of general metabolic processes, (2) that some types of sexual behaviour are independent of hormonal control, (3) that other patterns of sexual behaviour are specifically affected by hormonal stimulation, and (4) that where hormones affect sexual behaviour patterns, they do so by increasing or decreasing the sensitivity to external stimulation of cortical nervous circuits.

Another paper which is of particular importance, in so far as it presents a novel survey of newer knowledge, is Kochakian's review of the role of hydrolytic enzymes in some of the metabolic activities of steroid hormones. This paper shows that the metabolic effects of the steroids affecting protein anabolism work partly through the kidney, while those affecting protein catabolism function primarily through the liver.

A third most valuable review is Albright's on the effect of hormones on osteogenesis in man. This is a brilliant summary of the available knowledge on bone growth and of the effects of various types of endocrine stimulation on the process.

It is almost invidious to mention these three particular reviews. All the contributions to the volume are of the greatest importance, and it is to be hoped that future Laurentian conferences will be as well reported. Those who cannot attend the meetings will be even better pleased if the interval between conferences and the appearance of their Proceedings can be reduced. In the present instance, the date of publication is 1947, while the meeting took place in 1945.

S. ZUCKERMAN

PRACTICAL BRITISH FORESTRY

Practical British Forestry

By C. P. Ackers. Second edition. Pp. xviii + 394. (London: Oxford University Press, 1947.) 20*s*. net.

THE first edition of this book was reviewed in *Nature* of October 8, 1938; for the new edition, the chapters on nursery work and the future have been rewritten.

In the chapter on the future, the author discusses the changes brought about by the Second World War. He considers that the fully trained forester will be essential in the future, though in short supply, and that private forest owners will not be able to compete with Government for trained men. These statements are not quite in accordance with the existing position. There must be well over a couple of hundred men training at the present moment at the four universities, Oxford, Edinburgh, Aberdeen and Bangor, for the forestry degree. There are well over a hundred at Edinburgh alone. Out of this number it should be quite possible to provide good men for private forestry. The onus of taking this step does not lie with the educational centres, but with the private owners themselves. As has been advocated for a number of years now, if a few adjacent private owners of forest land would join together, they could easily afford to pay for the services of a man who has taken full training in forestry and done well at his examinations. In any event, wherever a man goes, to whatever Government service, he will have to learn the ropes during his first year or more before he can become fully efficient in carrying out the work of the department in question. This holds equally good for the young fully trained man appointed to private forestry; but the bogy that they will be carrying a 'dud' for three to five years is entirely without reason: and to sit and wait, as some owners of private estates have been doing for the last forty years in some cases, until they can pick up a fully trained man with full experience—obtained, it may be well asked, from where?—is not, it may be suggested, the way in which Mr. Ackers' aspirations will be fulfilled. That such trained men are fully as necessary to the management of large areas of private forests as to the large areas under the Forestry Commission is so obvious that it does not need discussion.

In the chapter on the nursery the following topics are dealt with: temporary nurseries; choice of a nursery site; shelter; cleanliness; soils, of course, and then seed and its extraction; period of sowing; depths of sowing and covering, and sowing distances; the collection of seed, and the dangers to which both seed and young plants are subject from birds, mice, moles, damping off and frost; the size of the plants to be put out in the forest; transplanting in the nursery from the seed beds; use of manures and rotation of areas in the nursery; season of planting; transport troubles and the use of sets and cuttings; packing and unpacking, and heeling the plants on arrival at their new position, previous to planting them out.

As in the former edition, the present one contains a number of good illustrations. The author may be congratulated on his presentation of the subject.

E. P. Stebbing

EARTHQUAKES AND VOLCANOES

Séismes et Volcans

Par Prof. J.-P. Rothé. (Que sais-je ?, No. 217.) Pp. 136. (Paris: Presses universitaires de France, 1946.)

THIS small book, with approximately the size and format of a British Penguin book, is believed to be the first written by Prof. J.-P. Rothé, of Strasbourg, the seismologist and son of the late Prof. E. Rothé, the distinguished French geophysicist. It is a worthy beginning. The book is accurate though semi-popular.

The five chapters concern the study of the visible effects of severe earthquakes, instrumental seismology and an earth model, earthquake geography, the supposed causes of earthquakes, and there is one chapter on volcanoes. The selection of material for the book has evidently been carried out with considerable care. Three earthquakes especially mentioned are the Provence earthquake of June 11, 1909, the Chilian earthquake of January 25, 1939, and the Roumanian earthquake of November 10, 1940. In a book of this sort it is a definite benefit to have large earthquakes mentioned which have occurred recently, even though there have been greater ones well described in such books as those by Dr. Charles Davison. The Chilian earthquake was undoubtedly one of the greatest earthquakes of the world and was so figured in *Nature* at the time. The macroseismic study of earthquakes still demands attention, for although it may be possible for an earthquake to start in a volume approaching a point, yet the mechanics of plane faulting figure largely both in the immediate cause and effect of earthquakes. Hidden faults have been mapped by instrumentally determined earthquake foci.

The chapter on seismic waves states clearly the elementary ideas underlying earthquake-recording instruments and the records obtained from these, and points out named waves on the records. The paths of these waves are shown on an earth model. There are no mathematics in the chapter, and seismic prospecting is confined to two pages. Seismologists and seismic prospectors will look forward to the promised book by the Rothés which is now being prepared.

The general outline of earthquake geography including deep-focus earthquakes as proved by Scrase is well described, and the regional earthquake geography of two well-explored regions, California by numerous American seismologists and the European Alps by J.-P. Rothé, is ably summarized. I myself feel that more modern attention to such subjects as are dealt with in "La Géologie Séismologique" by Montessus de Ballore would amply repay the time spent.

The 'causes' of earthquakes is a thorny subject, especially where it links up with isostatic theory. Epeirogenic and orogenic movements are considered and emphasis is placed on structure. The convection hypothesis, which incidentally assumes finite viscosity at moderate depths in the earth, is dealt with in conjunction with the gravity axis of Vening Meinesz near the Dutch East Indies. The theory of Wegener concerning moving continents is also mentioned.

Any theory of the origin of earthquakes must be capable of explaining the known facts of earthquake geography, such as the circum-Pacific belt and the South European–Asiatic belt, together with the limited distribution of deep-focus earthquakes and the gradual deepening of foci as we go from Spain via the Pamirs to Java. Seismology as an independent science is still young and has made great strides during the past forty years. That there are more problems to answer is a spur to those working on the subject. That the science is growing quickly is seen by the fact that the latest use of microseismic movement as a storm-centre locator at sea, and thus the use of the seismograph as a meteorological instrument, is not mentioned in Rothé's book.

Volcanoes are associated with earthquakes in the minds of people probably because both are catastrophic and unpredictable, and because both often occur in the same countries. Apart from both being associated with 'young' mountains, they have little else in common. This is made clear in a very concise terminal chapter in this admirable little book.

The books in this series "Que sais-je ?", published by the Presses universitaires de France, together form a popular modern encyclopædia on most branches of human thought. Sixty-eight volumes on pure science are mentioned on the cover. The general idea is commended to publishers of British Penguin and other low-priced books. Ernest Tillotson

X-Ray the City!

The Density Diagram: Basis for Urban Planning. By Dr. Ernest Fooks. Pp. 108. (Melbourne: Ruskin Press, 1946.) 12*s*.

IN this essay on the general principles of town-planning, Dr. Fooks, emphasizing that population density should form the starting point for urban planning, reviews the methods already suggested for measuring the density of population in urban areas and then suggests a new method which would enable a comparable analysis of different cities to be made, free from the confusion of arbitrary administrative boundaries which constitute the major defect in density figures in relation to a whole urban or metropolitan area when considered as a basis for urban development or rehabilitation. To overcome this defect, Dr. Fooks proposes to introduce clearly defined notions for expressing the environmental factor of urban living conditions and for measuring population distribution, and to illustrate the distribution of the population within urban areas by means of the diagram of population density in its various forms, based on the distance grid. He would then replace the vague overall density figures by distance-density figures and distance-density factors; and superimposing on a city plan a circular distance grid, and calculating the densities for individual segments of each concentric ring, he obtains a rational area density diagram which can be used effectively, if not universally, to implement the sociological approach to planning of which Lewis Mumford, F. J. Osborn, T. Sharp and Ebenezer Howard have been such eloquent exponents.

The various functions and facilities of a town can also be analysed on this grid basis, and quite apart from the international adoption of the method for which Dr. Fooks pleads, its interest and bearing on the various proposals for new and satellite towns in Great Britain need scarcely be stressed further.

The book is well produced and illustrated, and an excellent bibliography also enhances its general appeal, apart from its value as a scientific tool.

R. BRIGHTMAN

Alternating Current Electrical Engineering

By Philip Kemp. Seventh edition. Pp. ix+660. (London: Macmillan and Co., Ltd., 1947.) 25*s*. net.

THIS is essentially a students' text-book. It has already served, in six editions, many generations of students and should in the new edition continue to enjoy a well-merited popularity. A good deal of new material has been introduced and considerable sections of the text have been re-written.

In its scope and treatment this book is particularly suitable for use in connexion with National and Higher National Certificate courses, and it should also serve as an introductory text-book for engineering degree courses.

The difficult task of selecting the subject-matter has, in general, been well done; the exclusion, for example, of electronic phenomena and apparatus except in relation to mercury arc rectifiers. It is, however, questionable whether, having regard to present practice, the twenty-five pages devoted to rotary converters are justified.

In a book covering so wide a range of material the treatment of many topics is necessarily somewhat superficial, but in general the essentials are emphasized and a satisfactory picture presented. There are, however, occasional cases of lack of clarity of expression, as, for example, where it is stated on page 281 that "The advantages of hydrogen as a cooling medium are reduced windage and ventilation losses, due to the density of the gas". The treatment of fundamental matters is in the main thorough and satisfactory, but it is regrettable that such an important question as the sign convention which determines the 120° phase displacement of three-phase currents or voltages receives rather scant attention.

J. G.

Die hormonalen Aspekte des Fortpflanzungsprozesses

Von Dr. Jules Samuels. Pp. v+152. (Amsterdam: Holdert und Co., N.V., 1946.) n.p.

Die Hormonversorgung des Fœtus

Von Dr. Jules Samuels. Pp. vii+320. (Leiden: E. J. Brill, 1947.) n.p.

DR. SAMUELS is a gynæcologist and clinical endocrinologist of Amsterdam, and believes that the development of the fertilized ovum is under the direct control of the gonadotrophic hormones of the pituitary and chorion. He also believes that the thyrotrophic factor of the pituitary is identical with the luteinizing factor, and that both the sperm and the ovum contain a store of gonadotrophic substances. These views are a series of speculative and somewhat obscure conclusions derived from a general review of the literature. They are at variance with the more usually accepted conclusion, derived from experimental study, that the gonadotrophic substances exert an influence only on the pre-fertilization phases of development of the gametes. The burden of proof of Dr. Samuels' theses rests upon his shoulders, and until he can provide experimental support for his views they are scarcely likely to command more than occasional interest.

The Gemmologists' Compendium

By Robert Webster. Second edition. Pp. 241+20 plates. (London: N.A.G., Ltd., 1947.) 15*s*.

IT is ten years since this Compendium first appeared. Much additional matter has been incorporated in the new edition. The extensive glossary which constitutes Part 1 includes not only definitions of precious and semi-precious stones, and the trade names by which they are sometimes known, but also explanations of the various technical names used in connexion with the scientific study of gem stones. It has been enlarged, and now occupies one half of the book. Part 2 also has been extended, and deals very thoroughly with the optical, physical and chemical properties and characteristics of precious stones, and the technical methods by which these properties can be determined. Numerous tables of optical and physical constants are included, and there is also a section on artificial gem stones and the methods by which they can be recognized. Among the illustrations are twenty excellent plates, nine of which are coloured. Irrelevant matter of the type often found in books on gem stones, relating to their history and æsthetic value, has been completely omitted; but the book contains a vast amount of accurate and useful technical information arranged in a compact and convenient form. It is primarily intended as a *vade mecum* for jewellers and traders in precious stones, to whom it should prove invaluable; but it also forms a very useful ready-reference work for all in any way interested in gem stones, whether in a professional or amateur capacity.

CROSS-LINKING IN POLYMERIC SYSTEMS

By Dr. G. F. BLOOMFIELD

THE mechanical properties of a natural or synthetic polymer are profoundly affected when the van der Waals' intermolecular forces are supplemented by stable chemical linkages (cross-linkages) between the polymer molecules. In synthetic polymers, cross-linking may generally be brought about either as an essential part of the polymerization reaction, or by chemical modification of the polymer subsequent to polymerization; but cross-linking in natural rubber can only be accomplished by the latter method. Although cross-linkages in synthetic rubbers could be introduced during polymerization if desired, they are, in fact, excluded so far as possible; hence, as with natural rubber, it is necessary to carry out the cross-linking reactions on the polymer itself. In a recent series of lectures at the Royal Institution, London, various types of cross-linking mechanisms and their effect on the properties of polymers were discussed. Dr. H. P. Staudinger dealt with the cross-linking of vinyl polymers, the present writer discussed the structural modification of high polymers by vulcanization, with particular reference to rubber, and Dr. L. R. G. Treloar described the relation of mechanical properties to the degree of cross-linking in rubbers. Phenol-formaldehyde resins, in which the role of cross-linking reactions is rather less clear, were surveyed by Mr. E. G. K. Pritchett. My thanks are due to the board of the British Rubber Producers' Research Association for permission to contribute to this series of lectures and to prepare the following summary of them.

Permanent cross-linkages prevent irreversible flow and so contribute essentially to the reversible character of a deformation. Resistance to plastic flow, to thermal deformation and to solvents is thereby increased. A low degree of cross-linking, that is, less than one cross-linkage per polymer molecule, is insufficient to impart any real resistance to deformation, since the interlinked molecules still behave essentially as a linear, although highly branched, molecule; but as soon as two or more cross-links per molecule are introduced, there results a network in which flow is impeded. A high degree of cross-linking, on the other hand, leads to a highly rigid structure.

In order that rubber-like elasticity may be realized, some compromise is necessary between flow and rigidity, excessive cross-linking leading to a complete loss of rubbery characteristics.

Vinyl polymerization provides a useful means of studying the effect of cross-linking on the physical properties of polymers, particularly the flow properties, if the second-order transition temperature, *Tm*, can be taken to indicate the onset of viscous flow. A close relation between *Tm* and the average number of vinyl monomer molecules between cross-link junctions can be established. Cross-linking may be accomplished either by co-polymerizing bi- and tetra-functional monomers (for example, styrene with divinyl benzene, methyl methacrylate with allyl methacrylate), or by chemical reaction of a linear polymer containing reactive substituent groups with a substance of low molecular weight (for example, a copolymer of methyl acrylate and maleic anhydride is treated with ethylene glycol). In the first category the properties of the product may range from solubility and fusibility to complete insolubility and infusibility, depending on the relative amount and on the nature of the cross-linking agent in the co-polymer. Although in its initial stages the process of cross-linking with tetra-functional monomers can be interpreted by the kinetics of co-polymerization as applied to bifunctional monomers, where the relative amounts of the monomers and the relative reactivity of their double bonds are the determining factors, a full kinetic interpretation becomes extremely difficult, once inter- and intra-molecular reactions between polymer chains occur as part of the growth process in addition to the four growth reactions which are possible between polymer radicals and monomers. Fundamental differences in the polymerization mechanism arise when the degree of cross-linking is sufficient to give a gel due to a three-dimensionally interlinked network structure, for although the polymerization-rates are not significantly changed when the concentration of the cross-linking reagent is low, there is a marked increase in rate, coinciding with the appearance of the gel, when more of the cross-linking component is used.

Considering that termination is a bi-molecular reaction with respect to polymer radicals, the high viscosity of the medium—which is infinite once gel formation has occurred—will restrict diffusion of, and reduce collision between, polymer radicals, thus reducing the termination-rate; while propagation, involving diffusion of, and collision with, monomer, is little affected.

In order to exercise some measure of control over cross-linking by copolymerization, it is desirable to select types of double bond of widely different reactivities within the cross-linking molecule, the ideal being to produce a linear molecule by polymerizing the vinyl bonds, and then to promote a cross-linking reaction involving the less reactive bonds by a rather more drastic treatment. In practice, polymerization is first conducted to a point short of gelation, and the resulting syrup is used for casting or impregnation. An outstanding advantage of the new technique is that it requires no high-pressure equipment, and is accordingly very suitable for the fabrication of structures of considerable size.

A particularly undesirable form of cross-linking in vinyl polymerization is that responsible for 'popcorn' formation, in which small particles resembling popcorn grow rapidly with considerable volume expansion. 'Popcorn' formation is determined mainly by temperature and the proportion of cross-linking agent, consequently control involves both of these two factors. 'Popcorn' can itself initiate fresh 'popcorn' growth in virtue of its hydroperoxide content, or as a result of electronically stabilized radicals becoming reactive.

In cross-linking by chemical modification subsequent to polymerization, it is necessary that the polymer should contain functional groups (for example, ethylenic linkages) or reactive substituents (for example, halogen, hydroxyl, carboxyl).

An important aspect of cross-linking by chemical reaction is that comprising the whole field of rubber vulcanization; in fact, any reagent which is capable of providing intermolecular linkages between two or more polymer molecules is capable of vulcanizing rubber. The properties of the resulting vulcanizate, however, depend not only on the nature and number of the cross-linkages, but also on the possibility of side reactions and on the treatment necessary to promote reaction, and consequently they vary widely.

Rubber vulcanizing agents fall into two classes: those giving rise to radical reactions leading to carbon-carbon cross-linkages, and those which affect bridging through the agency of a bifunctional atom or molecule which itself forms the cross-linkage. The simplest example of carbon-carbon linking is provided by photogelling; cross-linking reactions of benzoyl peroxide, diazoaminobenzene and other reagents which decompose thermally to give free radicals are believed to follow a similar course. Bifunctional reagents include dinitroso compounds, azodicarboxylates, hydrogen sulphide, dithiols, sulphur chloride, and, most important in technical rubber practice, sulphur. The essential cross-linking reaction of sulphur consists in the establishment of a polysulphide bridge between two of the originally unsaturated molecules, with loss of one of the original double bonds and a displacement of the other. A necessary prerequisite of a cross-linking agent is that it shall react intermolecularly. The 1 : 5 diene system in rubber is, however, particularly prone to form intramolecular cyclic linkages when the reagent contains only one or two atoms between its reactive ends, and sulphur is no exception. The formation of tetrahydrothiopyrans has been demonstrated in the reaction of sulphur with small polyisoprenic molecules, and the low efficiency of sulphur as a cross-linking agent for rubber is undoubtedly to be attributed, at least in part, to its participation in cyclic linkages of the tetrahydrothiopyran type. A contributory cause of the low efficiency of sulphur is its participation in polysulphide rather than monosulphide cross-linkages. Rubber vulcanization is consequently very susceptible to small amounts of auxiliary substances capable of promoting intermolecular rather than intramolecular linkage, or capable of promoting monosulphide rather than polysulphide cross-linkages. Certain accelerated vulcanizates accordingly exhibit a much higher efficiency of cross-linking, although they still fall short of the theoretical maximum of one cross-linkage for each sulphur atom incorporated.

From the theoretical point of view, a vulcanized rubber is visualized as a three-dimensional network of molecules, the mechanical properties of which may be calculated by the methods of statistical thermodynamics. The physical basis of this approach is the assumption that the individual chains (or portions of molecules between successive junction points) are in a state of random thermal fluctuation of form, by virtue of the relative freedom of rotation about single bonds in the chain. This kinetic basis provides a reasonably satisfactory quantitative background for such physical properties as the form of the stress-strain relations in any type of strain, the effect of progressive vulcanization on tensile strength, the optical double refraction due to strain, and the principal phenomena of swelling in diverse liquids. By the use of certain simplifying assumptions it is possible to derive the following force-extension curve for a vulcanized rubber:

$$F = (\rho RT/M_c)\,(\alpha - 1/\alpha^2), \qquad (1)$$

where F is the tensile force, referred to the original cross-section, α is the ratio of the stretched to the unstretched length, ρ the density and M_c the 'molecular weight' of the chains between successive points of cross-linkage. Two interesting features of this equation are worth noting: first, the form of the stress-strain curve is determined by $(\alpha - 1/\alpha^2)$, and should therefore be the same for all rubbers, whatever their chemical constitution; and secondly, the modulus $(\rho RT/M_c)$ should be inversely proportional to M_c, the chain-weight between points of vulcanization, or alternatively, directly proportional to the number of cross-links.

Generally speaking, these theoretical predictions have been borne out experimentally. For a series of rubber-sulphur vulcanizates Gee observed a direct proportionality between modulus and percentage of combined sulphur, while Flory, in a comprehensive investigation of a range of butyl rubbers, obtained close agreement with the slightly modified formula

$$F = \rho\,\frac{RT}{M_c}\left(1 - \frac{2M_c}{M}\right)(\alpha - 1/\alpha^2) \qquad (2)$$

(M is molecular weight before vulcanization, M_c is molecular weight between junction points), in which the effect of terminal chains connected to the network at one point only is allowed for.

The swelling of rubbers by liquids is a phenomenon closely related to the mixing of two liquids. For a good swelling agent it is found experimentally that the absorption of the solvent is accompanied by very little change of energy. It is, however, accompanied by a very large change of entropy. Equilibrium swelling is achieved when the entropy increase due to the absorption of an additional small quantity of liquid is balanced by the entropy decrease due to the expansion of the elastic molecular network. Both the entropy of mixing and the network entropy can be calculated, and in this way it is possible to predict quite accurately how the maximum swelling will depend on the degree of cross-linking. Since the modulus also is determined by the degree of cross-linking, it follows that there should be a close relation between the modulus and the maximum swelling for a series of rubbers of different degrees of cross-linking. The quantitative relation worked out by Flory indicates that the modulus should vary inversely as the five-thirds power of the maximum swelling ratio—a relation which was found to be very closely borne out by Flory's data for butyl rubbers.

A phenomenon which is at first sight rather surprising, and for which, until recently, no explanation had been given, is the rapid fall in the breaking strength of natural rubber vulcanizates which occurs when the degree of cross-linking is increased beyond the optimum value. In a recent publication by Gee, evidence is brought forward which indicates that the effect may be explained in the following way. With increasing cross-linking the modulus continuously increases, and at the same time the elongation at break tends to fall progressively. But with reduced extensibility there is reduced molecular orientation and therefore very probably a reduction in the degree of crystallization. It is this reduced crystallization which gives rise to the reduction in tensile strength, since the crystallites have the effect of introducing strong binding forces between the molecular chains.

In the field of thermosetting resins, the role of cross-linking reactions is by no means so well established as in vinyl polymers and in rubber. Although the conception of cross-linking by methylene groups at the *p*-positions of the benzene rings is widely accepted, there are difficulties in the general application of this principle, since it is not at all certain that hydroxyl groups may not also be involved in the thermosetting reaction; and it is noteworthy in this respect that *p*-cresol resins show some thermosetting properties. Models indicate that methylene-linked structures are extremely rigid, since rotation of the benzene rings is very restricted sterically ; thermosetting linkages may possibly involve only a few of the benzene rings, so giving a plausible explanation of the low tensile strength of phenolic resins. An entirely new conception proposed by E. G. K. Pritchett envisages a mechanically interlinked rather than a chemically cross-linked structure, the extreme rigidity rendering the substance insoluble and infusible.

SALMON AND ANIMAL MIGRATION

By Dr. A. G. HUNTSMAN

Fisheries Research Board of Canada and University of Toronto

MORE than two thousand years ago, Aristotle wrote that all the actions of animals are for breeding, for feeding and to avoid extremes[1]. Clearly such motivations of migration satisfy those who ask why animals migrate ; but have they been verified and are they verifiable ? Are they still accepted as explanations of migration, the only problem being to discover how the animal can accomplish wonderful feats ? Has such an attitude been successful in elucidating migration ? The statements that for birds "this question has been extolled as a mystery of mysteries"[2] and that for the salmon migration is accomplished by "an instinct which man cannot comprehend"[3] are not reassuring.

If the matter is not yet clear, it may be because the proper approach has not been used. Perhaps migration should be considered merely as wandering, as was the original meaning. Facts against the prevalent ideas have long been known[4]; but no attempt seems to have been made to develop theories to include them, except as divorced from 'true migration', which has the idea of purpose either of the animal or of 'Nature'. It is not clear how we can verify the animal's purpose, and, as to Nature's purpose, it may be a mistake to assume that the animal's behaviour should be useful for survival, rather than merely not incompatible with survival of some of the race somewhere. If migration is merely wandering, that is, changing the place of abode, the problem is when and whither will an animal wander in view of its nature and of the conditions to which it is exposed. There has been a growing tendency to treat the matter thus objectively, which may permit accurate prediction.

For more than a decade, the Fisheries Research Board of Canada has been intensively studying the salmon (*Salmo salar*) as a somewhat representative fish. This study has provided the main facts with which we are attempting to develop a true science of fish migration.

No simple method of salmon behaviour will permit accurate prediction, since they behave most variously, as the following examples show. They may or may not spawn as parr before moving from the locality where they were spawned. On metamorphosing into smolts in the spring, they fail to spawn in that year and may or may not spawn in subsequent years up to the fifth. Usually, parr remain in streams, smolts and kelts (adults after spawning) descend, and near-spawning adults ascend ; but salmon may or may not descend to or ascend from the sea as parr[5], as smolts, as near-spawning adults and as kelts[6]. Clearly, the idea that their migrations are between breeding grounds in rivers and feeding grounds in the sea is inadequate. Some differences in behaviour have been ascribed to differences in original nature (sub-species or races) ; but for none of these has the original nature of the individuals been shown to be different, while correlations with environmental differences are evident and experiments fail to show that offspring of those behaving differently will behave differently under the same conditions, for example, for descent to the sea, that is, "migratory and non-migratory races"[7] or for time of return to streams, that is, "early and late running races"[8].

One theory that fits the facts, but that can be only part of the complex whole, is quite simple. It is that in the rapid water of a stream the fish is carried down (as it must be more or less) in its descending, and swims actively up (as it must) in its ascending migration, these being the only directions in which stream fishes can migrate. The well-known upstream orientation of fishes, or rheotaxis, which may or may not be elicited by the flowing water, depending upon the conditions, and the more or less active swimming of the fish are all that the theory requires. Underyearling salmon have been found to vary sufficiently to separate into two groups when placed in a rather strong shallow current—those that ascend and those that descend—but they all head upstream. Similarly, when with a strong freshet in the rivers the salmon in the sea left the east coast of Sutherland near Brora for the rivers, 'droppers', that is, salmon that had ascended the rivers and remained there for some time, but had dropped down again, appeared in coastal nets[9].

When entering the smolt stage, for which descent is typical, salmon behave most variously. With higher, that is, swifter water, more descend[10,8]. Some descend quickly, some very slowly, and some fail to descend ; yet they would all leave the stream in a few hours if they merely kept up from the bottom and headed downstream. Smolts marked as they left Forest Glen Brook for the large North-East Margaree River, Nova Scotia, in the spring of 1938, arrived at a trap fifteen miles down that river in from 1 to 28 days or more. It is judged that they all could, if headed right, have descended in 12 hours. In swift water they descend tail first swimming vigorously upstream, and they sometimes ascend rapids, as may be seen when they near a trap placed in swift water. That in slow water descending fish all head downstream into a trap may mean nothing more than that all the others, if swimming faster than the water flows, are certain to be moving upstream, since the narrowness of the stream prevents movement any distance in directions other than up and down. In a lake, roaming near the surface would be apt to take them near enough to the outlet for the current to act.

In September and October of 1945, smolts were still to be found above beaver dams in Holmes Brook near Moncton, New Brunswick, in spite of freshets that were thought to have brought them down. This finds explanations in observations by Mr. C. W. Andrews in trapping smolts on the neighbouring Pollett River. With quite low water in 1944, smolts known to be in the pool above the trap failed to descend during the forty-three subsequent days of operation of the trap and no rise in water. In late evening he saw them to have descended to the brink of a shallow rapid, and they moved back up to the pool by morning. Clearly, when near the surface and down to this rapid in the evening, strong rheotactic reaction due to their nearness to the bottom[11] caused them to swim upstream more rapidly than the current carried them down. With deeper water, they would face less stimulus when at the surface and the current would be stronger. He showed experimentally in 1946 that increase in water-depth at the rapid from four to twelve inches or more resulted in descent of smolts into the trap. In work in progress, underyearling salmon in round rearing pools are seen to migrate downstream, swimming with the current, in a zone of weak current up from the bottom, when in poor condition and at unfavourably high temperature. On these and other facts is based the conclusion that salmon descend when they both wander about and fail to react strongly enough in current to remain upstream. Evidence fails of salmon at any stage heading downstream in response to strong current.

Upstream migration is more easily understood, since fishes react to current by heading upstream. Salmon may ascend from the sea a year before spawning. Even when congregated at the river mouth, they frequently fail to ascend when ascent is easy with low, slowly flowing water, but ascend quickly in spite of the greater energy required with the increasing flow of a freshet (even artificial), unless the flow is quite strong[12]. Also, they ascend at times at least a short distance when the river water is so warm that they are killed by heat stroke[13]. On these and other facts is based the conclusion that salmon ascend when they both wander about and are sufficiently stimulated to swim upstream in rapids. The stimulus may come from increase in stream flow, from wandering of the salmon into more rapid waters or in other ways.

Even a stream in heavy flood has relatively quiet water at intervals where salmon will remain if resting on the bottom. It will depend upon how they move and how the water moves as to whether or not they migrate when active. Rheotaxis is the reaction of stream fishes that permits them to continue living in streams when they move about, their swimming upstream counterbalancing the current which would otherwise carry them out. This orientation is effected through relation with the bottom, even to frequent contact[11], which relation diminishes and disappears with increase in distance of the fish from the bottom.

A one-way current and a variable counter-current reaction by the fish form a proper basis for Meek's[14] denatant-contranatant theory of migration. Salmon are clearly to some extent both denatant (going with the current) and contranatant (going against the current) at all stages, so that the theory is applicable to them in one-way freshwater streams of sufficient strength and shallowness, as observation readily shows. In pools with deep, very slowly moving water, evidence for it fails and other factors must operate. Meek's theory has been used to explain migration of sea fishes, but proper evidence seems to be lacking, even for its action in estuaries. The facts given us as to the movement of salmon in estuaries, even shallow ones, are that they move inwards with flooding tide, that is, with, not against, the current. We have failed to get evidence of contranatant migration in the sea of either herring or salmon except in restricted tidal rapids with the fish not far from the bottom.

In general, movements of the salmon in the sea seem to be in all horizontal directions and more or less to and fro, as shown by the facts of their capture and of recapture of tagged fish. Their movements are clearly determined by the conditions they meet. They become inactive with the near zero (° C.) temperature of winter. Feeding actively as the water warms in the spring, they apparently do not roam and are not caught until they are ceasing to feed, which happens as early as May for large fish in eastern Canadian waters, but not until August for post-smolts, which corresponds with their relative fatness. They tend to hold position in rapids, which results in their collecting in channels and at river mouths. With steep salinity gradients, they tend to keep in water of low salinity, as the facts of their capture and of recapture of tagged fish show, which results in their reaching rivers. Also they tend to keep in water like that of the home stream[15], which is apt to take them sooner or later to the home stream, if far from it.

With such behaviour, they collect in the river outflow as the season progresses, but do not necessarily ascend. Some stimulus seems to be required for them to do more than swim sufficiently to hold position at the river mouth. A freshet may start their ascent, which is directed by rheotaxis. Underyearling salmon in a trough ascend quickly when stimulated by a local rapid increase in flow from lowering of the surface level downstream, although ascent then requires more effort. Adult salmon, when stimulated by the increased flow of a freshet, will for the most part not ascend when the current is strongest at the height of the freshet, but only as the current weakens. When sharp, stimulating, artificial freshets were made in the Moser River, Nova Scotia, in the dry season of 1942, more than twice as many salmon entered as were to be expected from counts of smolts and adults for the preceding three years[11], with the water generally so low that the fish could be readily caught in the evening on the rapids by poachers who made rough traps or mazes of stones for the purpose. With such freshets in the somewhat wet season of 1943 and with the native grilse having been marked the previous year as smolts, from one quarter to more than one half of the entering grilse were unmarked and presumably foreign fish[16], the proportion rising with advance in the season and particularly with heavy floods that doubtless brought in fish that were farther out to sea. Even through the spawning period, with continued absence of freshets from summer to the December freeze-up in 1946, salmon did not appear in traps operated on Holmes Brook, North River and Bennett Brook above the main Petitcodiac River, as they had done in previous years in going to spawning grounds, even though some were in the main river from midsummer[17]. If salmon must be stimulated to go upstream to spawn, should they be used as the chief example among fishes for true migration, defined[18] as "a racial custom, enregistered in the animal's constitution"?

With pressure of a dense population, planted salmon spread more widely, as planting experiments have shown. The facts indicate that the brook trout (*Salvelinus fontinalis*) shows this factor by failing to migrate down to the sea when heavy fishing lessens population pressure. The room required to stop migration changes with increase in size of fish, so that large fish are generally found in lower, larger waters. Planting of tagged kelts above Shubenacadie Lake has just shown extent of descent to large lakes or the sea to be correlated with the size of the fish.

I am deeply grateful to many colleagues who, with other ideas, have kindly responded to appeals for criticism, greatly aiding this presentation of the matter.

SUBMICROSCOPIC STRUCTURE OF THE BACTERIAL CELL, AS SHOWN BY THE ELECTRON MICROSCOPE*

By Dr. STUART MUDD

School of Medicine, University of Pennsylvania

THE wall of the bacterial cell is solid. The cell-wall may maintain its approximate shape after cytolysis; on breaking it may present a jagged line of fracture[1]. Within the cell-wall, and normally doubtless closely applied to it, is the cytoplasmic membrane enveloping a fluid or potentially fluid protoplasm. In electron micrographs the protoplasm often is appreciably separated from the cell-wall[2]. This is doubtless a shrinkage artefact due to desiccation in the electron microscope, which operates in a high vacuum. The protoplast and in particular the cytoplasmic membrane are stained and visible, the cell-wall unstained and not seen, in routine bacteriological preparations. Flagella, if present, arise from the protoplast and pass through the cell-wall, at least in vibrios. They are of uniform diameter somewhat characteristic of the bacterial species. They are not artefacts or mucous threads[3]. Capsules, as in the case of the pneumococcus, are extracellular gels surrounding the cell-wall[4].

Combination of bacterial antigens with antibodies may be directly observed with the electron microscope. Specific antibodies combine with somatic and flagellar antigens of non-capsulated bacteria to form surface deposits, respectively, on the cell-wall and flagella[5]. Non-specific components of serum (complement) may be adsorbed secondarily on the antigen-antibody complex[2]. Antiserum permeates the capsular gel of the pneumococcus; antibody combines with homologous capsular antigen and non-specific serum components are adsorbed; the swollen gel resulting is opaque to electrons[6].

Study of the internal structure of the bacterial protoplast has been retarded by the 'opacity' to electrons (diffuse scattering of electrons) of the protoplast, in particular of Gram-positive species, and by insufficient contrast of structures within the protoplast. In the special case of the sporulation and spore germination of an aerobic bacillus (*Bacillus mycoides*), Knaysi, Baker and Hillier[7] have revealed much additional detail by the use of a research model electron microscope operating at higher than ordinary voltage (150 kv.).

Knaysi and Baker[8] have also discovered an elegant method of making internal structure more apparent. *Bacillus mycoides* is grown in a nitrogen-free glucose-containing medium, buffered with sodium acetate. Under these conditions the electron-scattering ribonucleic acid of the cytoplasmic membrane and protoplast is reduced to a minimum, and two types of internal structures are revealed. The first are opaque bodies 0·22 by 0·29 μ to 0·43 by 0·50 μ in diameter; one to six of these are found in each cell; these bodies are present in all stages of development; they divide; they are included in the forespore when sporulation occurs; they take nuclear stains. They are interpreted as nuclei.

The second type of bodies are thin, each with circular or elliptical outline; they are 0·08 to 0·17 μ in diameter; a few to about forty are present per cell. "They are part of the cytoplasmic membrane and, except when they appear homogeneous, they cannot be structurally differentiated from the rest of that membrane. Both seem to consist chiefly of a net-work of beaded threads and granules, probably representing complex molecules." Electron micrographs of *Bacteroides funduliformis* by W. E. Smith, Mudd and Hillier also show a finely reticulated structure of the bacterial protoplasm[9].

The structure thus far made manifest in the bacterial cell, even with the aid of the electron microscope, is much simpler than the remarkable synthetic capacities of bacteria would seem to require. Cells of many kinds of bacteria, furnished only with water, salts, glucose and simple sources of carbon and nitrogen, can synthesize proteins, complex carbohydrates, lipids, ribose and desoxyribose nucleic acids, growth accessories and enzymes, all organised into characteristic and reproducible protoplasmic systems. The cell can reproduce itself and divide within half an hour at body temperature. These feats of chemical synthesis and organisation, which cannot be duplicated by the finest chemical laboratories in existence, are accomplished within a cell a few microns in length and less than a micron in diameter. The plain facts would seem fantastic if they were not so familiar.

W. Seifriz, K. H. Meyer and others[10] have pointed out that the elastic and thixotropic properties of protoplasm imply a three-dimensional lattice of elastic and solvated protein molecules or micelles. The width and thickness of extended molecules of ordinary proteins (about 10 A. by 4·5 A.) are at, or just beyond, the present limit of resolution of the electron microscope, when full resolution is taken advantage of by use of the techniques of shadow-casting[11], or of surface replica[12]. Globular protein molecules[13] and fibres composed of a small number of aggregated, extended protein molecules are detectable under favourable conditions with the electron microscope. The electron micrographs of bacteria cited above and those of Porter, Claude and Fullam[14] of the hyaloplasm of fibroblasts are compatible with the reticular protein framework which has been postulated as necessary to explain the physical properties of protoplasm.

It may be useful to proceed in imagination beyond the present visual evidence of fine structure. The interstices of the reticulum may be supposed to be filled with an aqueous phase. The simultaneous occurrence of complex reactions, involving energy utilization, synthesis, and organisation of the materials elaborated, implies means of keeping the reactions in proper temporal and spatial relation to each other, and implies organisation equivalent to an efficient system of transport and logistics. Substrates and enzymes must be brought together, the structural units of proteins must be synthesized and brought to the 'templates' at the surfaces of which further syntheses may be supposed to be determined; completed molecules must be added in their appropriate places to cell-wall, cytoplasmic membrane, nucleus, or even capsule or flagella, all in orderly, rapid and reproducible sequence.

---

* From a Symposium on Electron Microscopy at the Nobel Institute of Physics, Stockholm, Sweden, July 16, 1947, in connexion with the Sixth International Congress for Experimental Cytology.

Necessary segregation of reacting systems may be effected in part by the internal organisation of the submicroscopic particles present in protoplasm[10]. Some of the requirements of segregation and of transport may be supposed to be met by films of lipid or of lipoprotein across the interstices of the fine reticulum of the protoplasm. Lipid-aqueous phase interfaces tend to adsorb polar–non-polar molecules and particles and to transport them along the interface from regions of low to regions of higher interfacial tension[15]. The effects of oriented molecules in such interfaces on the orientation and distribution of molecules in the adjacent phases may be supposed to be additional factors in organisation[16].

Such considerations furnish only an imaginative sketch, in vague and general outline, of some of the features of the fine structure of bacterial protoplasm. Are there reasonable grounds for hope that electron microscopy may throw light on the actual fine structure of protoplasm? There are such grounds. The micellar and macromolecular fine structure of protoplasm is within the powers of *resolution* of even present-day electron microscopes. Analysis of the ultra-structure of nerve axoplasm[17] and of various fibrous structures[18] has indeed made significant progress. The problem of preparing specimens sufficiently thin so that fine structure is not overlaid and obscured, and with sufficient contrast so that fine structure is detectable, without essential alteration of the natural structure, has thus far only been partially achieved in a few favourable instances. Techniques of increasing contrast by selective combination with chemicals containing atoms of high atomic number[18,19] have been explored to the point of showing them to be feasible; but their exploitation has only begun. It is challenging at least to realize that study of submicroscopic fine structure with the electron microscope is limited by technical difficulties rather than by the inherent nature of image formation, as is the case with the light microscope.

OBITUARIES

Dr. Henri Deslandres, For.Mem.R.S.

By the death on January 15 of Henri Deslandres, born in Paris on July 24, 1853, the Paris Academy of Sciences has lost its senior member, and astronomy and spectroscopy have lost one whose active researches go back more than sixty years. Destined for an army career, he resigned in 1881 when a captain in the Engineers and devoted himself to spectroscopy and astronomy. His earliest papers on band spectra date from 1885, and he continued his work until last year, publishing his last paper in the *Comptes rendus* within a week of his ninety-fourth birthday. Even at that age he suggested taking up fresh work as soon as sufficiently accurate material was available. Laws connecting the wave numbers of separate lines in the same band and of the heads of different bands are associated with his name.

In 1889 Deslandres was appointed an assistant at the Paris Observatory and placed in charge of the spectroscopic investigations. He at once began work on radial velocities of stars, on planetary rotations, on cometary spectra, and on solar physics. In his work on the photography of prominences and features on the sun's disk in monochromatic light, he developed the spectroheliograph independently of Hale, to whom, however, priority of invention was awarded; but he also designed the *spectro-enregistreur des vitesses*, which showed the sight-line motions of the gases giving the features in the monochromatic pictures. Instead of a very narrow second slit and continuous motion, he used in this instrument a wider second slit and obtained a series of stationary photographs of successive narrow sections of the sun's disk. How good his technique was, and what beautiful results he could obtain with both types of instruments, were amply shown after he became director of the Meudon Observatory on the death of Janssen in 1907. His work gave an insight into the circulation taking place in the solar atmosphere in disturbed regions, and laid the foundation for the excellent studies now continued by his colleague and successor, Dr. L. d'Azambuja. In particular, he examined the differences between the layers of the solar atmosphere photographed in different narrow sections of the lines $H\alpha$ and K. His work on sunspots and connected solar phenomena led to a study of the connexion with terrestrial magnetic storms, and of the nature of the charged particles emitted by the sun.

Deslandres was appointed director of the Paris Observatory in 1927 and retired in 1929. He was elected an associate of the Royal Astronomical Society in 1904, received its Gold Medal in 1913 and became a foreign member of the Royal Society in 1921. He received the Bruce Medal of the Astronomical Society of the Pacific and was a foreign member of many national academies. He remained mentally alert to the end of his long life, and died of pneumonia after several months of growing physical weakness.

We regret to announce the following deaths:

Prof. Selig Hecht, professor of biophysics in Columbia University, on September 18, aged fifty-five.

Sir Arthur Huddleston, C.M.G., O.B.E., director of the Royal Technical College, Glasgow, since 1933, and previously a member of the Sudan Political Service, on February 11, aged sixty-seven.

NEWS and VIEWS

Importation of Books into Britain

Lord Balfour of Inchrye, speaking in the House of Lords on February 19, directed attention to the effects of the present restrictions on the import of books into Britain. He said that we cannot afford to fall behind in the application of modern scientific developments, and due to the difficulty in publishing books there is danger that Britain will be cut off from the exchange of ideas and knowledge. He suggested the imposition of a maximum time-limit for dealing with applications for import licences, that the permissible quantities of book imports be increased, and that there should be blanket licences of specified amounts for universities, libraries and approved scientific bodies. Lord Chorley, Lord in Waiting, in reply, said that the President of the Board of Trade is discussing with representatives of the learned institutions their difficulties in obtaining books, particularly from the United States. As a result of those discussions, an increase in the quota may be granted, though he would not hold out a promise that it would be up to the 200 per cent of the pre-war amount which had been suggested.

Conscription and Industry

An article by D. R. O. Thomas (*J. Inst. Personnel Management*, 29, No. 293; September–October 1947) directs attention to the possible effect on industrial efficiency of the withdrawal of large numbers of young men for national service requirements. Under the Act, which becomes operative on January 1, 1949, men between the ages of eighteen and twenty-six years are to be called up for national service for a period of twelve months, the actual call-up age being eighteen, and thereafter each man will serve 5½ years with the reserve, during which he is required to do sixty days training. This, and the new developments under the 1944 Education Act in respect of the raising of the school age to sixteen years and the establishment of county colleges, will mean that industrial organisations will be faced with the prospect of starting youths in employment at sixteen years and afterwards releasing them for one day in five, up to eighteen years, when they will disappear altogether for twelve months. On return to employment, the young man will be required to do two weeks Service training per year for 5½ years, which, together with his annual holiday, may mean his being absent from industrial employment for one month in every twelve until he is about twenty-five years of age.

Remembering, too, that the effects of the lower birth-rate will be strongly felt within the next decade, these national service requirements are bound to cause difficult problems for management in industry. It is essential, therefore, as Mr. Thomas points out, that the national service period should be used as efficiently as possible and should fit carefully into a scheme of training and experience, from school-leaving age to twenty-one or so, which will provide a useful apprenticeship to the responsibilities of work and citizenship. To offset the loss of industrial time, industry itself must make the best possible use of the time available in providing young people with specific training for their jobs. The rest of the article makes cogent suggestions for training schemes for various types of recruits and indicates how the difficulties of deferment for apprentices and students can be overcome.

U.N.E.S.C.O.: New Appointments

The following new appointments in U.N.E.S.C.O. have recently been announced:

Dr. Clarence E. Beeby, director of education in the New Zealand Government, to be assistant director-general, concerned chiefly with the co-ordination of educational activities. Dr. Beeby, head of the New Zealand Delegation to the Second Session of the General Conference in Mexico City (November–December, 1947), was also chairman of the Programme and Budget Commission and thus is already well familiar with the aims and the activities of the Organisation.

Prof. Emile Auger, member of the French Atomic Energy Commission, to be head of the Natural Sciences Section. Prof. Auger was a member of the French Delegation to the General Conference of U.N.E.S.C.O. and has for the past year been a member of the Executive Board of the Organisation. He will replace Dr. Joseph Needham in that post. Dr. Needham, after nearly two years service with U.N.E.S.C.O., is returning to his post at the University of Cambridge.

Prof. Pedro Bosch Gimpera, to be director of the philosophy and humanistic studies section. Prof. Gimpera was formerly Dean of the Philosophy Department of the University of Barcelona. He has lately been professor in the University of Mexico.

Mr. Gordon Menzies (Australia), to be director of administrative services.

War-time Work of the American Academies

"The Ethnogeographic Board", by Wendell C. Bennett (*Smithsonian Misc. Coll.*, 107, No. 1; 1947), is a history by one of its members of an organisation for harnessing the academic institutions of the United States to the war machine. It was set up by the National Research Council, the American Council of Learned Societies, the Social Science Research Council and the Smithsonian Institution in June 1942 and continued until the end of 1945. It was not an official body and it was financed and supported by the organisations which founded it, particularly the Smithsonian; but it was very largely used by the Armed Forces and Government departments, and is described as a "clearinghouse for Government needs and Academic knowledge". It consisted of a directorate, situated in the Smithsonian, which was the Washington office of the Board and did most of the work, and the Board proper, which was advisory. It produced reports on various areas, and lists of people with knowledge of foreign parts, and it undertook special projects, of which a booklet called "Survival on Land and Sea" was one of the most valuable and was widely circulated to the Armed Forces in the Pacific theatre. It had no equivalent in Great Britain, where the type of information supplied was collected by Service departments, such as the naval and military intelligence organisations and the Inter-Services Topographical Department.

Dr. Bennett gives a straight account of the Board and its activities, pointing out its strength and its weaknesses, and makes suggestions as to how such a body should be organised if needed again. (One of these is that it might have a better name!) Some points are of general interest, particularly the first paragraph on war-time Washington, beginning "Fo[illegible] the millions who milled around Washington in t[illegible] first half of 1942, no statement about the fabu[illegible] confusion could ever be adequate . . .", and [illegible] following statement about the search for peopl[illegible] could compile special reports: "The Board found that those who were still in their academic settings managed to find time for something within their competence which was directly concerned with the war. Once a scholar was in Washington it was hard to get much out of him, and once he got into uniform, however sedentary the assignment, it was almost impossible."

Science and Society in Ancient China

In his Conway Memorial Lecture, "Science and Society in Ancient China", delivered on May 12, 1947, Dr. Joseph Needham attempts to sketch a pattern of the organisation of Chinese feudal society and its relation to Western European society (London: Watts and Co., Ltd. 2*s*. net). While the Taoist hermits who withdrew from human society to contemplate Nature had no scientific method, they tried to understand Nature in an intuitive and observational way, and the earliest chemistry and astronomy in Asia had Taoist connexions. In ancient China, although Taoist empirical mysticism favoured the development of science, Confucian ethical rationalism was antagonistic, and it could not be claimed that all through history rationalism had been the chief progressive force in society. While inventions and technological discoveries such as gunpowder, paper, printing, the magnetic compass and efficient animal harness, which changed the course of civilization, were made in China, modern science and technology did not develop them. Dr. Needham points out that the status of military technology may deeply affect the crystallization of social philosophy, and that a moral question such as slavery may be closely connected with technical factors. Philosophical and ethical thought, he believes, can never be dissociated from their material basis, and he thinks that Chinese civilization was basically inhibited from giving rise to modern science and technology, because the society which grew up in China after the feudal period was unsuitable for these developments. Dr. Needham concludes by commending a closer study of the great classics of Chinese philosophy and of the parallel course of technology in China.

Interchange of Technical Publications in Sheffield

A report on the progress made during the last year by the Organisation for the Interchange of Technical Publications in Sheffield was presented to the fifteenth annual general meeting held in the Central Library, Sheffield, on December 2. This Organisation controls a system of co-operative borrowing of books, periodicals and other records, between the numerous special libraries in the Sheffield area. Recent activities of the Organisation have been directed to other ways of assisting research and development now that the effective pooling of technical publications and information has been operating for many years. The annual report shows that 1,459 publications were borrowed last year. A survey of the location of foreign patents in British libraries was undertaken; through the Association of Special Libraries and Information Bureaux, the Patents Office was asked to close the gap in indexes and abridgments to British patent specifications left during the War; and an inquiry made as to the mount of assistance obtainable from the Neder- ndsch Instituut voor Documentatie en Registratuur foreign patent searches. At the annual general ting, it was decided to ask the Board of Trade ave the mass of documents relating to war-time German industry held by the Technical Information and Documents Unit of the Board abstracted and indexed on similar lines to the work done in the United States by the Air Technical Intelligence and to have the more important items translated on the advice of technical experts. It was also recommended that files of the microfilms taken by the Board of machine drawings selected from this collection should be deposited with the leading technical libraries of Britain. Twenty-four firms and seven societies and institutions now belong to the Organisation.

Textile Laboratories at Leeds

The International Wool Secretariat has for the past ten years given increasing support to the University of Leeds for research on wool; it has now made a gift of £10,000 for the purchase of equipment for the new Textile Laboratories, all the apparatus to be utilized for the benefit of the wool industry. At present, five men hold Secretariat fellowships in the Department, and in addition, a grant of £1,600 a year has been made during the past two years in support of research in textile engineering. The number of workers engaged on these and other wool research projects is now so great that a severe strain has been thrown on the laboratory accommodation. In 1946, however, the Worshipful Company of Clothworkers of London made a grant of £20,000 towards the building of new wool research laboratories, and a start on the work was made in December 1947. The ground floor of the new building will be used to extend the Cloth Finishing Section of the Department, while the first floor will contain several laboratories for wool research workers. The second floor will take the form of one large laboratory, which will be used to give undergraduates practical experience of the applications of chemistry at all stages of the manufacture of wool textile materials. The grant of £10,000 from the International Wool Secretariat is for the equipment of the new building and will be used to purchase the most modern types of machinery for the Finishing Section, as well as the special apparatus which will be needed by research workers and undergraduates.

Old Scientific and Natural History Books

The following catalogues have been issued by Messrs. Bernard Quaritch, Ltd., of 11 Grafton Street, London, W.: No. 644, Books and Periodicals relating to Mathematics, Physics and Allied Sciences including two small collections on Accountancy and Mining; No. 650, Books and Periodicals on all Branches of Zoology, Geology, Palæontology and Botany; and a Catalogue of Books and Manuscripts issued to commemorate the One Hundredth Anniversary of the firm of Bernard Quaritch: 1847–1947. Noteworthy among these is Messrs. Quaritch's centenary catalogue. This is of especial interest to booklovers on account of the introductory matter, in which is related the growth of the firm from small beginnings in October 1847, in a shop in Castle Street, Leicester Square, London, to its present status as a business of world-wide repute. There is also a portrait of the founder, who died in 1899, and a brief sketch of his life, prepared by his daughter, Mrs. Charlotte Quaritch Wrentmore. As might have been anticipated, this catalogue is worthy of the occasion. It is a lavishly illustrated production, containing six coloured and some forty black-and-white plates. Among more than two hundred books listed for sale there is a number of items of scientific interest, including the *editio princeps* of Pliny's "Historia naturalis", printed at Venice in 1469; a first edition of Newton's "Principia" (another copy is offered in Catalogue 644); an exceptionally fine copy of Hooke's "Micrographia"; and the first illustrated edition of the "Hortus Sanitatis", printed at Mainz in 1491. Many interesting works are listed in Catalogues 644 and 650, which contain 423 and 1,926 items, respectively.

Another catalogue of interest is that of Dr. E. Weil, c/o National Provincial Bank, 9 Market Place, London, N.W.11. This is No. 10, "From Alchemy to Chemistry and Pharmacology", and it includes also a section with sixty-nine works relating to the early history and development of photography. Among several works by or relating to Robert Boyle listed in this catalogue is Johann Seger von Weidenfeld's alchemical work "De Secretis Adeptorum" (London, 1684), in which the author made use of an unprinted manuscript by Boyle. Dr. Weil suggests that this manuscript, entitled "De Magisterio sive de investigatione secreti occulti Lullii", may be one of the Boyle manuscripts burned in 1688, of which, hitherto, no titles were known. This work, dedicated to Robert Boyle, will, it is stated, be described in Dr. J. F. Fulton's next addenda to his bibliography of Boyle.

Food Calories

THE Food and Agriculture Organisation of the United Nations has issued an interesting brochure entitled "Energy-Yielding Components of Food and Computation of Calorie Values" (from the Organisation, Washington, D.C.). This is the report of a Committee on Calorie Conversion Factors and Food Composition Tables, and contains much useful information. An appendix deals with organic acids as sources of available calories, and this includes a useful bibliography. The Committee considered the main causes of difference between estimates of energy-yielding components and of energy values, and concluded that the ideal procedure is separate determination of all the substances contained in food which contribute energy, combined with accurate assessment of their individual physiological values and their interrelationships. The question of the protein value of nitrogenous constituents is not completely resolved. Discussing carbohydrate values of foods, the Committee considers that at present the use of 'carbohydrate by difference' is justified, provided that its limitations are understood and appropriate procedures are used for deriving energy values. The value of the report cannot, however, be appreciated unless it is read.

Earthquakes during the Last Quarter of 1947

THE last quarter of 1947 opened with an earthquake on October 3 which was felt most strongly at Santarem, caused some alarm in the working-class districts of Lisbon, and damaged many buildings in Lisbon, Cascaes and Estoril. There were about ten other strong earthquakes in October in various parts of the world, including the one felt strongly at Coroni in southern Greece on October 6, and another felt strongly and causing some property damage 40 miles south-west of Fairbanks in Alaska on October 16. The latter had an aftershock on October 20. During this month, thirty-eight small earthquakes and earth tremors were felt in New Zealand, the greatest being on October 13 from an epicentre at lat. 44·2° S., long. 169·0° E., felt over most of the South Island. November opened with an intense earthquake on November 1, 150 miles north-east of Lima in Peru. This caused considerable property damage and also was responsible for the deaths of at least fifty-three people. Strong aftershocks of the earthquake occurred on November 7 and 25. Of the fourteen other strong earthquakes during the month, that on November 23 in south-west Montana was felt in Montana and Idaho. In December, some thirteen strong shocks occurred, the European ones being felt on December 13 in the Pyrenees, on December 20 in the Tirol and on December 25 at Lago d'Iseo in Italy. Seismological reports have been received from Beograd (Yugoslavia), Durham, Kew, United States Coast and Geodetic Survey and Jesuit Seismological Association, Strasbourg, Stuttgart, Wellington (New Zealand) and Zurich and the Swiss observatories.

International Conference on Sleeping Sickness

AT a conference convened jointly by the French, Belgian and British Colonial authorities and recently held at Brazzaville, French Congo, to which the Governments of Portuguese territories in Africa, of Southern Rhodesia and the Union of South Africa also sent delegates, arrangements were made for the uniform mapping of the whole of Africa south of the Sahara to show the incidence of trypanosomiasis in man and domestic animals and of the various species of tsetse fly which transmit it. It was also agreed to establish, at Brazzaville and Leopoldville, a joint bureau for the rapid exchange of information on methods of controlling the disease, and to set up in Europe a scientific committee on an international basis to supervise the organisation of research. These conclusions will now be forwarded to the Governments of all the African territories as recommendations for a concerted effort to control the disease and to work towards its gradual elimination.

Society of Chemical Industry: Annual General Meeting

THE Society of Chemical Industry will hold its annual general meeting in Edinburgh during July 12–17. This is the first annual general meeting since the War to be held outside London, and the first since 1927 to be held in Edinburgh. The president of the Society, Dr. L. H. Lampitt, chief chemist and a director of Messrs. J. Lyons and Co., Ltd., will deliver his address on July 13. On July 14 there will be a lecture by Sir John Anderson, who has been awarded the Messel Medal for 1948 of the Society. The Lister Memorial Lecture will be given on July 15. This Lecture was founded to commemorate the influence of the work of the late Lord Lister on the pharmaceutical industry in Edinburgh and was endowed in 1944 by two Edinburgh firms of drug and fine chemical manufactures, Messrs. J. F. Macfarlan and Co. and Messrs. T. and H. Smith, Ltd. The first lecturer, in 1944, was Sir Alexander Fleming. This year's Lecture will be devoted to biochemistry. A series of papers will be presented dealing with industrial chemical aspects of a number of the principal industries in the east of Scotland. They will describe some of the industrial research which has already been done in Scotland and will point to the possibilitie for the future. In many cases the lectures will b followed by visits to the factories and installations [illegible] the various industries. Lectures will be given [illegible] Prof. S. Watson, principal of the East of Scot

College of Agriculture; Dr. G. A. Reay, of the Torry Research Station, Aberdeen; Mr. E. R. H. Edge, of Messrs. Alex. Pirie and Co., Aberdeen, on paper-making; Prof. W. H. Melville, of the University of Aberdeen, on rubber; Dr. I. A. Preece, of the Heriot-Watt College, Edinburgh, on brewing; and Mr. H. Corteen, director of the British Jute Trade Research Association of Dundee, will speak on "Research Developments and Applications to Textile Industries in East Central Scotland". The meeting is being organised by the Edinburgh and East of Scotland Section of the Society, the honorary secretary of which is F. J. Bolton, 17 Wester Coates Avenue, Edinburgh 12.

International Conference on Powder Metallurgy

THE Steirmark Branch of the Association of Austrian Chemists is arranging an International Powder Metallurgy Conference to be held during July 12–16 in Graz. It is hoped, by lectures and discussions, to furnish a comprehensive picture of the position and problems of the scientific, industrial and economic aspects of powder metallurgy and allied subjects. The organising committee consists of Prof. G. Jantsch, Technische Hochschule, Graz; Dr. R. Kieffer, Metallwerk Plansee, Reutte, Tirol; Prof. O. Kratky, Universität, Graz; Prof. G. F. Hüttig, Technische Hochschule, Graz. Further information can be obtained from Dr. C. Sykes, Brown - Firth Research Laboratories, Princess Street, Sheffield; or Mr. M. Littman, Compound Electro Metals, Ltd., 42 Pall Mall, London, S.W.1.

International Sericultural Congress

THE Seventh International Sericultural Congress will be held at Alès (Gard) in the Cevennes during June 7–13, and will be followed by an International Silk Congress at Lyons. The Sericultural Congress is being organised by the French National Institute of Agronomic Research; the president is Prof. R. Delmas, professor of sericulture in the École Nationale d'Agriculture, Montpellier, and the general secretary is M. Schenk, director of the Sericulture Research Station, Alès. The programme is being arranged in a number of sections covering scientific, economic and technical aspects of the subject. The Congress, which will mark the fiftieth anniversary of the research station at Alès, will be the first of so wide a scope since the Sixth International Sericultural Congress held in Paris during September 1878. Further particulars can be obtained from the Secrétariat-Général, Station de Recherche Séricoles, 28 Quai Boissier de Sauvages, Alès (Gard), France.

Conference on Rheology and Textiles

A CONFERENCE on "Rheology in the Textile Industries" has been arranged by the British Rheologists' Club in association with the Textile Institute, the Society of Dyers and Colourists, the Leeds area local sections of the Chemical Society and the Royal Institute of Chemistry, the Yorkshire Section of the Society of Chemical Industry and the Manchester and District Branch of the Institute of Physics, and will be held during March 19–20 in the Department of Textile Industries, University of Leeds. Further particulars can be obtained from Prof. J. B. Speakman, University, Leeds 2, or the honorary secretary of the British Rheologists' Club, Dr. E. W. J. Mardles, Royal Aircraft Establishment, Farnborough, Hampshire.

Announcements

AT a recent ceremony at the Royal Netherlands Embassy, London, the Netherlands Ambassador presented the insignia of Commander in the Order of Orange-Nassau (Civilian Division) in recognition of services rendered to the Netherlands during the War to the following, among others: Sir George Beharrell, chairman of the Dunlop Rubber Co., Ltd.; Sir Jack Drummond, sometime scientific adviser to the Ministry of Food; Dr. John Hammond, reader in agricultural physiology, University of Cambridge; Sir Raymond Streat, chairman of the Cotton Board.

THE following appointments in the University of Leeds have been announced: Prof. H. S. Ruse, professor of pure mathematics, to be head of the Department of Mathematics on the retirement of Prof. S. Brodetsky at the end of the present session; Prof. T. G. Cowling, professor of mathematics at the University College of North Wales, Bangor, to be professor of applied mathematics from October 1; Dr. N. H. Hartshorne, to be lecturer in chemical microscopy.

THE following appointments in the University of Sheffield have been announced: Dr. A. J. Gould, senior lecturer in the Department of Glass Technology; Dr. J. S. D. Bacon, lecturer in biochemistry; R. E. Davies, honorary lecturer in biochemistry; A. Jordan, honorary lecturer in clinical biochemistry.

A SYMPOSIUM on "Combustion and Flame and Explosion Phenomena" will be held at the University of Wisconsin during September 7–11. Papers will be presented on fundamental and theoretical aspects of combustion, technical research, combustion problems in jet propulsion, special fuels, etc. It is hoped to publish all the papers together within a few months of the meeting. Particulars can be obtained from Prof. Joseph O. Hirschfelder, University of Wisconsin, or from Dr. Bernard Lewis, U.S. Bureau of Mines, Pittsburgh 13, Pennsylvania.

THE Faraday Society is arranging one of its General Discussions, which will be held in the Department of Physics, University College, Southampton, during March 31–April 2. The subject will be "The Interaction of Water and Porous Materials", and the papers have been divided into four groups: (1) Fundamental Aspects; (2) Botanical Aspects: Mechanism of Movement of Solutions in Plants; (3) Zoological Aspects: Water-Protecting Properties of Cuticles; and (4) Permeability to Water and Water Vapour of Textiles and other Fibrous Materials. Papers will be issued in advance of the meeting and taken as read. Further particulars can be obtained from the Faraday Society, 6 Gray's Inn Square, London, W.C.1.

THE British Iron and Steel Research Association has now obtained a licence for erecting limited accommodation of temporary construction on a site at Meadow Street in Sheffield. At the present time the Association's investigations at Sheffield are divided between the Applied Science Department of the University of Sheffield (where there is an experimental rolling mill), the works of Arthur Lee and Sons, Ltd. (where there is a prototype backpull wire drawing machine), and elsewhere. The intention is ultimately to create a permanent building in which rolling, drawing and other similar researches will be centralized.

Formation of Derivatives of Thyroxine from Derivatives of Diiodotyrosine

THE observation of von Mutzenbecher[1] that traces of thyroxine are formed on incubation of an alkaline solution of diiodotyrosine was developed by Harington and Pitt Rivers[2]. These authors showed that the course of the reaction was greatly influenced by *p*H; the largest yield of thyroxine, amounting to 2·7 per cent calculated on the diiodotyrosine not recoverable at the end of the oxidation, was obtained at *p*H 10; at this *p*H the acidic groups of diiodotyrosine are 95 per cent neutralized. In highly alkaline solution, there was little destruction of diiodotyrosine and no thyroxine formation: at lower alkalinity (*p*H 8–9) the destruction of diiodotyrosine was very extensive and the formation of thyroxine was minute. In all experiments in which diiodotyrosine was oxidatively destroyed, tarry by-products appeared and the liberation of ammonia was evident.

It seemed reasonable to suppose that protection of the amino-group of diiodotyrosine by acylation would diminish the tendency towards oxidative destruction of the amino-acid, and might then favour the oxidative intramolecular coupling which is the essential step in thyroxine formation. As a preliminary test of this hypothesis, solutions of *N*-acetyl-*l*-diiodotyrosine were incubated at 37° for fourteen days, the *p*H varying from 6·5 (60 per cent neutralization) to 8·5 (90 per cent neutralization). At the end of the incubation, the solutions were made strongly alkaline and boiled under reflux to hydrolyse the acetamino-group; butanol separation then led to the isolation of thyroxine. The amounts of thyroxine formed were small, the maximum formation occurring at *p*H 7·5.

It had been noticed that during these incubations a white crystalline salt slowly separated. In a further experiment at *p*H 7·5, this salt was collected after fourteen days. After decomposition with acid and purification of the product by the method of Ashley and Harington[3], there was obtained N-*acetyl*-l-*thyroxine*, m.p. 227–228° (decomp.), $[\alpha]_D^{21}$ 25·7° (*c* = 4 per cent in a mixture of equal volumes of alcohol and *N* sodium hydroxide). Hydrolysis of this compound by heating with a mixture of 15 parts concentrated hydrochloric acid and 25 parts of acetic acid yielded *l*-thyroxine, $[\alpha]_D^{21}$ −5·42° (*c* = 3·3 per cent in a mixture of 2 parts alcohol and 1 part *N* sodium hydroxide); found: I, 62·0 per cent; $C_{17}H_{13}O_5NI_4$ requires I, 62·0 per cent. The yield of acetylthyroxine calculated on the acetyldiiodotyrosine destroyed was 15–20 per cent.

These experiments showed clearly that the reaction of oxidative coupling of two molecules of diiodotyrosine to form a diphenyl ether is not confined to the free amino-acid, but on the contrary is favoured by acylation of the amino-group; moreover, with the acylamino-derivative the coupling occurs most readily at the *p*H of body tissues. In view of the obvious bearing of this result on the question of the formation of thyroxine in natural proteins, it was desirable to extend the experiments to a derivative of diiodotyrosine in which both amino- and carboxyl-groups were blocked. The derivative selected was *N*-acetyl-*dl*-diiodotyrosylglutamic acid.

A preliminary incubation of this compound at *p*H 7·2, followed by hydrolysis and butanol fractionation, did indeed lead to thyroxine formation; but in this case no insoluble sodium salt separated and the ultimate yield was low. The experiment was therefore repeated at the same *p*H in baryta solution; under these conditions a barium salt soon began to separate and increased in amount until a month had elapsed. At this time it was collected and decomposed with acid, and the product crystallized from aqueous methanol. The N-*acetyl*-dl-*thyroxylglutamic acid* thus obtained formed fine needles, m.p. 195–200° (decomp.); found: C, 27·8; H, 2·77; I, 52·5 per cent; $C_{17}H_{17}O_5NI_4$, H_2O requires C, 27·3; H, 2·3; I, 52·6 per cent. Hydrolysis of this compound with a mixture of acetic and hydrochloric acids yielded pure *dl*-thyroxine and glutamic acid. The yield of *N*-acetyl-*dl*-thyroxylglutamic acid was 36 per cent after allowing for recovered starting material. It is clear, therefore, that combination in peptide linkage of the carboxyl group of diiodotyrosine favours still more its conversion at biological *p*H into thyroxine.

In the experiments just described, the final reaction mixture is relatively free from tarry by-products; it is therefore hoped that it may be possible to isolate an acylamino-compound corresponding to the side-chain lost from one of the molecules of diiodotyrosine participating in thyroxine formation; attempts in this direction are now in progress.

A full account of the work described above will be published elsewhere.

Condensation of 2:4:5-Triamino-6-hydroxypyrimidine with Glucose and Fructose

WE have been engaged for some time on a study of the condensation of 2:4:5-triamino-6-hydroxypyrimidine (I) with glucose and with fructose. As Ohle and Hielscher[1] have carefully established the optimal conditions for the condensation of *o*-phenylenediamine with glucose and with fructose in the preparation of tetrahydroxybutylquinoxaline, we have, from the outset, applied these conditions to (I). Glucose afforded a product (II) having $[\alpha]_D^{20°}$ approximately − 81·5° in *N* hydrochloric acid or in *N*/10 sodium hydroxide solution, while fructose afforded a substance (III) with a slightly higher specific rotation, $[\alpha]_D^{20°}$ approximately − 86·6°, under the same conditions. At this point, a paper by Karrer, Schwyzer, Erden and Siegwart[2] appeared describing the condensation of (I) with a variety of simple sugars using less elaborate conditions than ours. Their product from glucose had $[\alpha]_D^{20°}$ − 68·93°, and their product from fructose had $[\alpha]_D^{20°}$ − 46·0°, respectively, in *N*/10 sodium hydroxide solution; these figures are significantly different from ours, particularly in the case of the product from fructose. Although final conclusions were not reached, Karrer and his collaborators considered their products from glucose and fructose to be respectively (IV, or V ?) and (V, or IV ?), the constitution of their product from glucose being indicated as (IV) with some degree of certainty.

A Polysaccharide from Hydatid Cyst Fluid

A SEROLOGICALLY active polysaccharide has been isolated from hydatid cyst fluid from an infested sheep. A positive precipitin reaction was obtained with the serum from a patient suffering from pulmonary hydatid disease, when dilute solutions of this polysaccharide were used as an antigen. Serum giving positive and negative Wassermann results showed no precipitin reaction with this same antigen.

It is considered that this polysaccharide fraction of the hydatid cyst fluid is probably the specific antigenic factor.

A detailed report of the preparation of this fraction together with its properties will be submitted for publication at a later date.

Gas Discharges at Centimetre Wave-lengths

EXPERIMENTS have recently been described[1] showing that at frequencies of 2,800 Mc./sec. and 9,800 Mc./sec. the breakdown of air takes place at stresses some 30 per cent lower than the breakdown values for steady voltages, for gaps of a few millimetres. In order to extend the observations to longer gaps, experiments are in progress on discharges in cavity resonators, where the necessary stress can be built up over longer gaps. Power is obtained from a magnetron excited by 1 microsecond pulses applied either individually or at the rate of 400 per second.

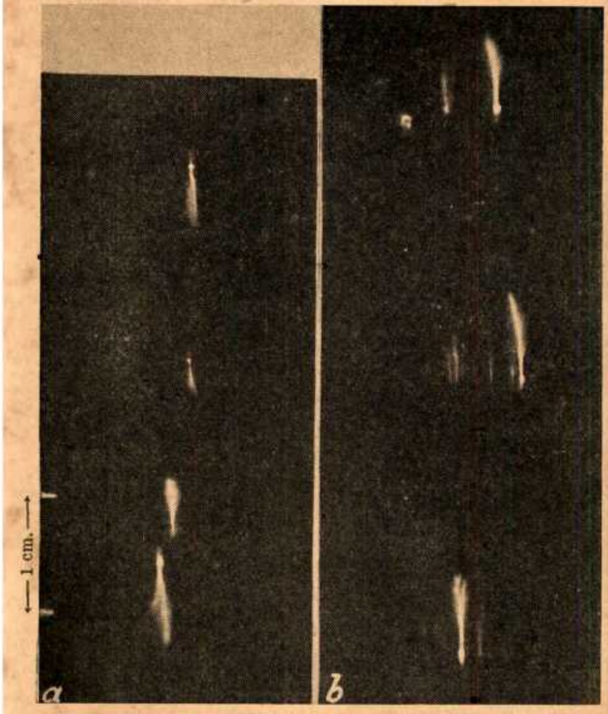

Fig. 1. PHOTOGRAPHS OF DISCHARGES IN A RESONATOR (*a*) WITHOUT IRRADIATION; (*b*) ONE ELECTRODE IRRADIATED WITH ULTRA-VIOLET LIGHT

The film was moved between successive discharges. Note that in (*b*) the discharge always starts from the same electrode and that subsidiary streamers are present. Electrode separation 1·44 cm.

The form of discharge obtained at atmospheric pressure is shown in Fig. 1, where it will be seen that the chief component consists of a bright spot on the electrode, together with a less intense tail across part of the gap. With repetitive operation, the gap is filled with a faintly luminous haze in addition. Occasional mid-gap streamers are observed for both individual and repeated pulses. Spectrographic observations show that the tail emits a nitrogen band spectrum, while the spot emits lines characteristic of the electrode material.

With 400-cycle pulses, as the pulse voltage is lowered, the time-interval between bursts of discharge increases and it is possible to determine graphically the pulse voltage V_0 for which the probability of starting the discharge becomes zero. For any pulse voltage greater than V_0, it is found that if sufficient *individual* pulses are applied a discharge eventually occurs, so that the breakdown voltage of the gap is the same for individual and for repeated pulses. Once, however, a discharge has occurred, the probability of breakdown within 1/400 sec. is increased, so that the 400-cycle pulses produce bursts of discharge, and a direct comparison of the ratio (No. of discharges)/(No. of pulses) for repeated and for individual pulses cannot be made.

Initial experiments, in which ultra-violet light from an auxiliary spark was applied immediately before the beginning of the high-frequency pulse, showed that ultra-violet light has marked effects on the appearance of the discharge, and on the sparking probability, for single pulses. A comparison between the sparking probabilities, with and without irradiation, can be made directly. In agreement with earlier work[1], in which a radium source was employed, it is found that the voltage at which the sparking probability just becomes zero—the true breakdown voltage—is unaffected by irradiation: at higher voltages irradiation increases the sparking probability.

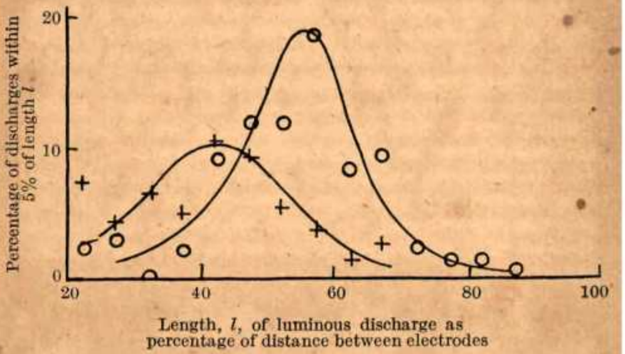

Fig. 2. DISTRIBUTION OF LENGTH OF DISCHARGES
○, one electrode illuminated with ultra-violet light; +, no irradiation

When the electrode surface is irradiated, the length of the luminous tails is increased, and shows less variation from pulse to pulse (Fig. 2). When, however, the ultra-violet light is concentrated in the gas (air) between the electrodes, numbers of mid-gap streamers are observed at each pulse, even when the typical spot and tail discharge does not occur—clearly a consequence of photo-ionization in the gas.

The observations are being extended to include an examination of the effect of changes in the duration of the pulse, the nature of the gas and the gas pressure on the discharge phenomena. It is hoped also to make cloud-chamber studies of the conditions preceding breakdown.

Grateful acknowledgment is made to the Council of the Durham Colleges for granting one of us (W. A. P.) a year's leave to pursue this work, and to the British Electrical and Allied Industries Research Association for financial support throughout the investigation.

Refraction Effects in Electron Diffraction and in Electron Microscopy

RECENTLY, Cowley and Rees[1] reported some interesting work on the fine structure of electron diffraction patterns of crystals of magnesium oxide, cadmium oxide, etc. (multiple rings or spots) by application of high-resolution electron diffraction cameras. They confirmed the view of Sturkey and Frevel, who suggested that this fine structure arises from refraction at the faces of the regularly shaped crystal cubes. If the normals of the faces by which the beam of electrons enters and leaves the crystal lie in the same plane with the beam and the normal of the net plane[2], one can derive an expression relating the angular displacement of the beam ε to the angles φ_1 and φ_2 (angle between face normal and incident and refracted electrons respectively):

$$\varepsilon = \theta - \theta_0 = \varepsilon_1 + \varepsilon_2 = V/2E(\pm \tan\varphi_1 \pm \tan\varphi_2)$$
$$\theta < \varphi < \pi/2 - \theta \qquad (1)$$

(V is inner potential, E is accelerating potential, θ_0 Bragg angle for $V = 0$). This deviation having values of 10^{-4} radians ($V = 10$ volts, $E = 50{,}000$ volts, $\varphi = 45°$) or 3×10^{-3} cm. at a specimen-plate distance of 30 cm., high resolution will be necessary to detect it.

This explanation is intimately connected with that given for the results obtained with electrolytically polished surfaces (Jacquet procedure) by electron diffraction and the electron microscope[3]. These surfaces are slightly waved so that the angle between the limiting face and the net planes (δ) has only a value of some degrees, whereas in the case considered above the faces are steeply inclined to the net planes. Therefore ε becomes greater and the same refraction effect will be observed by normal resolution.

Thus $\varepsilon = (\tan\delta + \theta_0)\left[\overset{+}{(-)}\sqrt{1 - \dfrac{V}{E(\tan\delta + \theta_0)^2}} - 1\right]$

($\sin\theta \sim \theta$, $\sin\theta_0 \sim \theta_0$). Generally, one can put $V/E < (\tan\delta + \theta_0)^2$ also for electrolytically polished surfaces. Thus it follows

$\theta = \theta_0\,(1 - V/2E\theta_0^2\,(1 + \tan\delta/\theta_0))$ [4] or

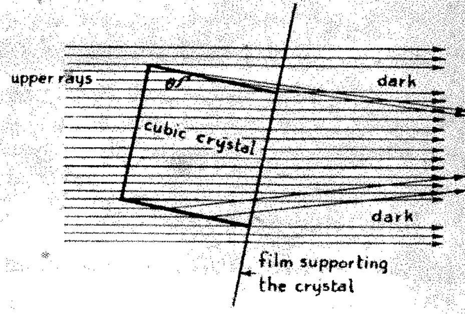
$$\varepsilon = -V/2E(\tan\delta + \theta_0). \qquad (2)$$

With $\delta \sim 5 \times 10^{-2}$ (3°) and $\theta_0 \sim 2 \times 10^{-2}$, one finds $\varepsilon \sim 15 \times 10^{-4}$, or half a millimetre at a plate-specimen distance of 30 cm., which can be seen without difficulty, $\tan\delta$ being always greater than 0 in the case of reflexion (there are always elevations transmitted), ε will be less than 0, or the reflected beam is displaced to smaller reflexion angles. If δ is continuously varying between 0 and $\delta_{\max}$, the patterns are enlarged to streaks as on electrolytically polished surfaces. For transmission patterns as referred to above, one has also $\tan\delta < 0$ and therefore $\theta > \theta_0$.

Between the angles φ, θ and δ exists the relation $\delta = \pi/2 - (\varphi + \theta)$. To show the transition from eq. 2 to eq. 1, one has to put $\varphi > \theta$ as supposed for the derivation of (1), and one obtains

$$\varepsilon = -(V/2E)\tan\varphi.$$

The total deviation is given by the sum of ε at entering and leaving the faces.



These considerations are also relevant to refraction effects in electron microscopy. A refraction effect may be of importance if well-shaped crystals, for example, cubic crystals, are transmitting electrons as shown in the diagram. The electrons being deflected by refraction out of their original direction, one would expect that the cube faces nearly parallel to the beam would appear as dark lines (a dark frame if the crystals are also somewhat tilted with their faces out of the plane of the paper). The refraction by the steeper faces is here neglected. Whether the refracted image is visible or not depends on the objective aperture and the inclination of the crystal. It seems to me that the dark bands which surround small inclined crystals of magnesium oxide[5] may be explained in such a manner. The size of these bands is given by the crystal dimensions in the primary direction and the angle of inclination.

At very small angles ($\theta \lessdot \theta_{\text{lim}} = \sqrt{V/E} = 0{\cdot}014$ at $V = 10$ volts and $E = 50{,}000$ volts) the rays, in the figure the 'upper rays', are totally reflected, which gives as above a transmitted (dark) and a totally reflected (intense) image, the latter being more deflected (2θ) than that normally refracted. Perhaps this effect would be found by a systematic study using crystals of greater dimensions, for which the bands are better resolved.

[2] If this condition is not fulfilled one has to take a more general formula derived by Cowley and Rees (ref. 1).

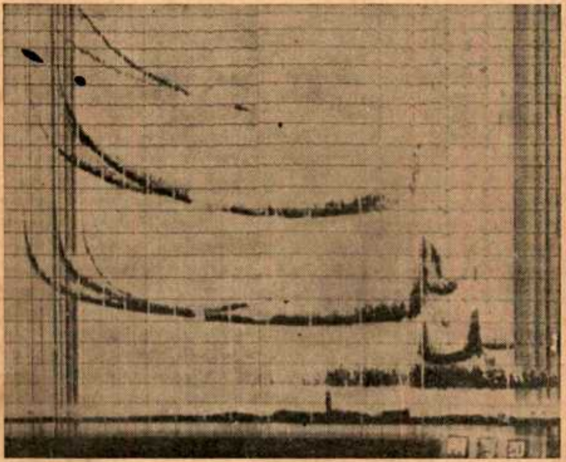
[3] Raether, H., *Métaux et Corrosion* (Jan. 1947).

[4] Kranert, W., Leise, K. H., and Raether, H., *Z. Phys.*, **122**, 248 (1944). In this paper the formula given for θ was $\theta = \theta_0\sqrt{1 - V/E\theta_0^2\,(1 + \tan\delta/\theta_0)}$, which had been derived by putting approximately $\theta + \theta_0 = 2\theta_0$: developed, it gives the exact solution 2. They are equivalent in the regions applied for the evaluation of electrolytically polished surfaces.

[5] For example, Heidenreich, R. D., and Sturkey, *J. App. Phys.*, **16**, 97 (1945), Fig. 1. Kinder, E., *Naturwiss*, **31**, 149 (1943). This effect must not be confused with the parallel strips of strongly inclined crystals the origin of which explains the dynamical theory, nor with the Fresnel diffraction strings in the out-of-focus image of a crystal edge.

Triple Magneto Ionic Splitting of Rays Reflected from the F_2 Region

A RECORD for 1700 hr. local time on November 9, 1946, from the Hobart $P'f$ recorder operating in the frequency range 1·5–13 Mc./s. is reproduced below.



The record shows the ordinary and extraordinary rays usually present from F_2 with critical frequencies of 7·6 and 8·5 Mc./s. respectively, as well as a third ray the critical frequency of which is 7·0 Mc./s. The critical frequencies of these rays correspond approximately to the Appleton–Hartree[1] reflexion condition $\mu = 0$ except that, neglecting collision, one would expect the third ray to have a critical frequency of 6·7 Mc./s. Discrepancies of about this magnitude and sign which are not ascribable to experimental error occur in all the 'triple split' measurements taken and may perhaps be accounted for if collision effects were included in the calculations. The possible existence of triple magneto ionic splitting in a layer where the variation of electron density with height is very rapid was first discussed by Mary Taylor[2], and the phenomenon has been observed by Toshniwal[3] and Liev Harang[4]; but the record shown is one of the best examples of it that we have seen.

Thirty-nine definite examples of this triple splitting have been observed in some 50,000 records spaced at regular intervals over a period of a year. Other records possibly showing this effect (quadruple and even higher multiple forking) have been discounted as examples of multiple magneto ionic splitting because of indications of stratification in F_2 or very spread echoes. The triple split records are generally accompanied by sporadic E ionization and seem more likely to occur under disturbed conditions. Triple splits have been observed at nearly every hour of the day, but they occur most frequently between the hours of 1700 and 2000. Occasionally they appear on the records over a period of several hours, starting or finishing as multiple forked records in the stratified layer. There appears on the Hobart data to be no evidence for the seasonal variation noticed by Harang. The figures for the number of occasions present (they may be either single occurrences or last for several hours) over twelve months are: 1946, September 2, October 4, November 3, December 0; 1947, January 0, February 3, March 5, April 1, May 0, June 2, July 5 and August 4. Further data on the occurrence of the phenomena will be analysed as they become available.

The records from the Hobart $P'f$ recorder are measured by the University of Tasmania for the Radio Research Board of the Council of Scientific and Industrial Research, and I would like to acknowledge the help received from that body in this and other ionosphere investigations.

Variable Source of Radio Frequency Radiation in the Constellation of Cygnus

COSMIC or galactic noise was discovered by Jansky[1] in 1931; but its exact origin has remained uncertain. It is generally supposed to originate from collisions in interstellar matter[2]; but there are divergencies between existing theory and experimental results, particularly at lower radio frequencies[3]. Hey, Parsons and Phillips[4] discovered variations in the intensity of galactic noise from the direction of the constellation of Cygnus, with a period of about one minute—suggesting that this particular radiation has its origin in a discrete source.

During the past three months, we have made a study of this region, mainly on 100 Mc./s., but also occasionally on 60, 85 and 200 Mc./s. The technique employed was to observe the region rising over the sea with aerials situated on a high cliff, as described by Pawsey, Payne-Scott and McCready[5]. Due to interference between the direct ray and the ray reflected from the sea, a lobe pattern is obtained which gives rise to a succession of maxima and minima. An estimate of the size of the source can be made from the relative heights of maxima and minima, and an accurate position found from the times of occurrence of minima.

Small aerial arrays were used—one or two Yagis—and considerable care was taken with receiver stabilization enabling receiver noise to be balanced out and the input signal amplified for presentation on a recording milliammeter. At 100 Mc./s. receiver fluctuations represented an input signal of less than 3×10^{-24} watts $m.^{-2}(c./s.)^{-1}$.

The general results of our investigations are:

(1) The variations from Cygnus originate in an area of less than 8′ angular width. This is an upper estimate and the source may well be effectively a point.

(2) The location of the source is R.A. 19 hr. 58 min. 47 sec. ± 10 sec. Dec. $+41° 41' \pm 7'$.

(3) The radiation consists of two components, one constant and the other showing considerable variation over short and long periods. In Fig. 1, a typical record of the source rising, the two components are separated by a dotted line. A record of the 'quiet' sun rising is shown for comparison in Fig. 2. The frequency in both cases was 100 Mc./s.; intensity scales are the same on both records.

(4) Observation on different frequencies shows that the intensity of the constant component has a shallow

It was found desirable to keep the length of the plug as short as possible, to ensure that air could readily pass through the powder when the meniscus became detached. This factor would no doubt set a lower limit to the size of particle measurable by the method, although the surface tension and density of the liquid can be adjusted to give the most favourable conditions.

The apparatus would seem to be readily applicable to other problems connected with particles; for example, the random packing of regular shaped bodies.

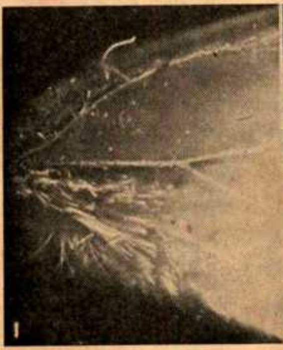
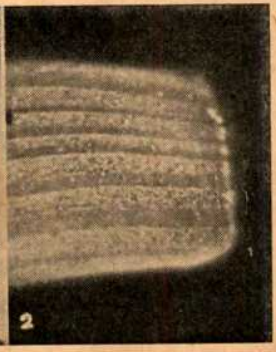
Surface Radiography with Alpha Rays

IT is well known that the short-lived atoms of radium A, B, C, and C′ are deposited on the surfaces of objects which come in contact with radon. Three of them, namely, radium A, C and C′, emit alpha rays. The emulsion of a photographic plate is blackened by these alpha particles. Their range in the emulsion is very short (maximum 50 μ). The geometric properties of the surface, for example, differences in the distance of various points of the surface of the object from the emulsion, cause a different blackening due to the alpha emission of the deposit on the surface. This enables us to develop a radiographic method which gives in a simple way a picture showing the structure of the surface.





A wing of a butterfly (*Vanessa io*) was exposed for two hours in a vessel (volume 70 c.c.) containing 1 mc. of radon. Afterwards the wing was put for 8 min. on the emulsion of a photographic plate ('Foma Repro'), and the plate then developed. Fig. 1 shows a positive copy of the original radiograph (× 3). With a microscope of low power the squamous structure of the wing can be seen in the picture. By the same method radiographs of polished surfaces of different kinds of wood were obtained; these show the fibrous structure of the wood (Fig. 2) (×3). Wood moistened before the exposure in radon gave better results.

Controls without exposure in radon gave no pictures.

A Suggested New Force Field for Molecular Vibrations

THE molecular force field which has been most successful in accounting for molecular vibration frequencies is the 'simple valency force field'. In many cases, however, this simple field has had to be modified considerably by introducing cross-terms. Most frequently these have been introduced empirically with the sole object of obtaining a good reproduction of the observed frequencies. This procedure is unsatisfactory, because it is often impossible to be sure of selecting the correct cross-terms from those that are possible. There have been a few more valuable attempts to modify the simple valency force field, and account for the cross-terms, which have been based on a more careful consideration of the forces, other than simple valency forces, that may exist in the molecule[1]. However, recently we have found that a new force field leads to more satisfactory results. We call this the 'orbital valency force field', and it differs from the older view in its treatment of angular distortions[2]; whereas the simple valency force field considers the bending angle by angle, the orbital valency force field treats it bond by bond.

In modern valency theory, directed chemical bonds are associated with directed atomic orbitals. Take boron tribromide as an example. The three bonding orbitals of the boron atom are of the sp^2 type and are arranged symmetrically in a plane[3]. Therefore, in the equilibrium configuration, the bromine atoms are arranged symmetrically around the boron atom. When a bromine atom is displaced at right angles to the B—Br bond, the overlap of its bond-forming orbital with that of the boron atom will decrease and there will be a force tending to restore it to its original position. For the motion to be simple harmonic the restoring force must be proportional to the displacement. Because the orbitals are symmetrical about their axes, the force constant will be independent of the direction of the displacement. That is, for boron tribromide, the same orbital valency force field bending constant may be used for the in-plane and out-of-plane bending. It is this that enables us to test the new field. For boron tribromide we use a potential energy function involving three constants: k_1 is the ordinary valency force field stretching constant; k_β the orbital valency force field bending constant; and $2A$ the second differential of the potential energy function (V') for the BrBr repulsion. $\frac{1}{R} \cdot \frac{dV'}{dR}$ (where R is the BrBr distance) also enters our formulæ, but this is put equal to $\frac{1}{13}$ of d^2V'/dR^2, which is the value it would have if $V' = a/R^{12}$, that is, if the repulsion between the bromine atoms is of a van der Waals' type[4]. $\frac{1}{R} \cdot \frac{dV'}{dR}$ is much smaller than k_1, k_β and A, so that its exact value is not of great importance. With $k_1 = 2{\cdot}385 \times 10^5$ and $k_\beta/r^2 = 0{\cdot}188 \times 10^5$ dynes per cm. the calculated frequencies are those given below:

Frequencies (cm.$^{-1}$)	$\nu_1 (A_1')$	$\nu_2 (E')$	$\nu_3 (E')$	$\nu_4 (A_2'')$
Obs. freq.[5]	279	806	151	372
Calc. freq.	279	815	151	372

The frequency of the in-plane bending vibration is ν_3 and of the out-of-plane bending ν_4. It will be seen that the average percentage error for all the frequencies is only $\frac{1}{4}$. Also the orbital valency force field accounts for the relative magnitudes of the two bending vibration frequencies. The average percentage error between calculated and observed frequencies for other AB_3 planar molecules and ions is: BF_3 : 0·1; BCl_3 : 1·45; $CO_3^{=}$: 0·2; NO_3^{-} : 3·4; SO_3 : 0·55. There seems no doubt, therefore, that the orbital valency force field provides a much more satisfactory force field than the simple valency force field which requires two unrelated bending constants for planar AB_3 molecules. We have also found that the orbital valency force field is better than the simple valency force field (both being combined with repulsion between the non-bonded atoms) for 'eight-tetrahalides' like CCl_4 and 'four-ions' like $SO_4^{=}$[6]. We are proceeding to apply the orbital valency force field to other molecules.

Band Spectrum of Aluminium Bromide

THE $^1\Pi - {}^1\Sigma$ system of AlBr near λ 2790 has been photographed in emission with high dispersion (0·6 A./mm.). Measurements of the Q heads have verified Howell's analysis[1]. Howell was, however, not able to make any definite observations on the isotope effect of the Q heads. Some of his Q heads, therefore, refer to the molecule $AlBr^{79}$, others to the molecule $AlBr^{81}$. On account of this, a new Q head formula has been calculated. Thus the band-origins of the molecule $AlBr^{79}$ can be represented by the formula :

$$v = 35879{\cdot}5 + 297{\cdot}2\,(v' + \tfrac{1}{2}) - 6{\cdot}40\,(v' + \tfrac{1}{2})^2 - 0{\cdot}527\,(v' + \tfrac{1}{2})^3 - 378{\cdot}0\,(v'' + \tfrac{1}{2}) + 1{\cdot}28\,(v'' + \tfrac{1}{2})^2.$$

The rotational structure of the 0,1 , 1,0 , 1,1 , 1,2 , 1,3 , 2,1 , 2,2 , 2,3 and 2,4 bands has been analysed. On account of the close structure, the bands were not resolved up to the heads. The analysis gives the following values for the band-constants :

$$B'_v = 0{\cdot}1555 - 0{\cdot}00216\,(v' + \tfrac{1}{2}) - 0{\cdot}000175\,(v' + \tfrac{1}{2})^2 \text{ cm.}^{-1}$$
$$B''_v = 0{\cdot}1591 - 8{\cdot}53 \times 10^{-4}\,(v'' + \tfrac{1}{2}) + 1{\cdot}4 \times 10^{-6}\,(v'' + \tfrac{1}{2})^2 \text{ cm.}^{-1}$$
$$D'_v = -\,[1{\cdot}8 + 0{\cdot}14\,(v' + \tfrac{1}{2}) + 0{\cdot}13\,(v' + \tfrac{1}{2})^2] \times 10^{-7} \text{ cm.}^{-1}$$
$$D''_v \doteq -\,1{\cdot}09 \times 10^{-7} \text{ cm.}^{-1}$$
$$r'_e = 2{\cdot}322 \times 10^{-8} \text{ cm.} ; \; r''_e = 2{\cdot}296 \times 10^{-8} \text{ cm.}$$

The observed rotational isotope separations agree well with those calculated, but the approximate formula $\Delta\nu_r = (1 - \rho^2)\nu_r$ cannot be used.

The calculated values of the separations of R and Q heads agree well with those observed.

The frequency ω_e has been calculated from Guggenheimer's formula[2]. This gives in the case of AlBr, $\omega_e = 370{\cdot}3$, in rather good agreement with the observed value $\omega_e = 378{\cdot}0$.

A more detailed account of the analysis will be published in the *Ark. f. Mat. Astr. o. Fys.*

Comparison of Metallographic and X-Ray Measurements of Retained Austenite

THE martensite reaction in steels has been studied by microscopic examination of polished and etched samples after the samples have been tempered for short periods of time. One etching reagent which has been used is a solution of 6 per cent nitric acid in alcohol, which is called 6 per cent nital. This etchant stains the martensite grey or black and leaves the austenite white.

In quantitative studies of the amount of austenite which was retained after quenching to room temperature, this etchant appeared to obscure some of the austenite when the specimens were quenched from austenitizing temperatures below 1750° F. (954° C.). In steels exhibiting temper brittleness, Cohen, Hurlich and Johnson have found that the addition of a wetting reagent called 'Zephiran Chloride' to a modified picric acid etch reveals a precipitate not shown by other etching reagents[1]. ('Zephiran Chloride' is a trade-mark of Winthrop Chemical Company, Inc., indicating its brand of a mixture of high molecular alkyl-dimethyl-benzyl-ammonium chlorides, the descriptive name of which is benzyl-trialkonium chloride, marketed as an aqueous solution containing 12·8 per cent 'Zephiran Chloride'.) Therefore, 1 per cent 'Zephiran Chloride' was added to nital in an attempt to increase the sensitivity of the nital. Although 6 per cent nital is a better etchant than 4 per cent nital for steels containing small amounts of austenite, it is necessary to reduce the amount of nitric acid in the etch containing 'Zephiran Chloride' to 4 per cent because the 'Zephiran Chloride' increased the speed of etching.

COMPARISON OF METALLOGRAPHIC AND X-RAY MEASUREMENTS OF AMOUNT OF RETAINED AUSTENITE AT ROOM TEMPERATURE (68° F., 20° C.)

Austenitizing temperature	Metallographic measurements Standard etch 6% nital	 Improved etch (4% nital and 1% 'Zephiran Chloride')	X-ray measurements
1450° F. (788° C.)	0	2·0 ± 1·0%	3·1 ± 0·2%
1550° F. (843° C.)	0	6·0 ± 1·0%	7·0 ± 0·4%
1650° F. (899° C.)	3·0 ± 3	14·0 ± 1·0%	14·0 ± 0·8%
1750° F. (954° C.)	17·0 ± 1	20·0 ± 1·0%	20·0 ± 1·0%

Critical measurements were made on a 1·1 per cent carbon, 1·4 per cent chromium steel, quenched into oil at 68° F. (20° C.) from a series of austenitizing temperatures listed in the accompanying table. X-ray measurements utilizing a new technique were made on these steels by Averbach[2]. Then the specimens were tempered for 10 sec. at 630° F., and were polished and etched. Quantitative measurements were made metallographically of the amount of retained austenite using a Hurlbut counter, described by Howard and Cohen[3]. The metallographic measurements with the improved etch were practically identical with the X-ray measurements, although the reproducibility of the X-ray results was better than that of the metallographic results, and the X-ray measurements revealed slightly more austenite than the metallographic measurements in steels containing 7 per cent or less retained austenite. It is considered that nital is improved by the addition of 'Zephiran Chloride'. However, the reason for the improvement has not been established yet.

Rh Genes Allelomorphic to *C*

The third allelomorph, C^w, at the C-c locus of the *Rh* chromosome was not recognized until a pure anti-C^w serum was found[1]; but its existence could have been demonstrated by testing several hundred samples of blood with a range of anti-C sera, for some of these sera are of the specificity anti-C and some, the majority, anti-$C + C^w$. It is not yet clear why the latter type of antibody may result from stimulation by the antigen C.

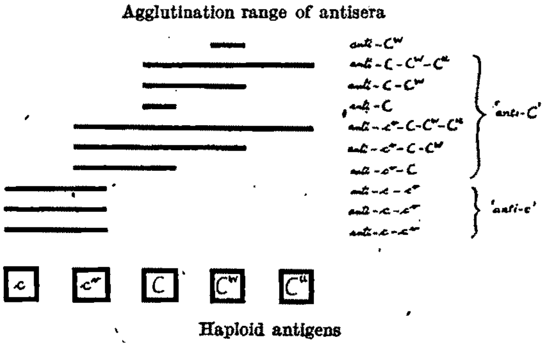
	anti	-D	-E	-e	-C^w	-c	'anti-C' -C	-C	-CC^w	-CC^w	-CC^w	-CC^w	Genotype
	Mother	+	+	+	−	+	−	−	−	−	−	−	*cDE/cde*
	Father	+	+	+	−	+	−	+	+	−	−	+	c^vDE/cde
c^v donor	1st son	+	+	+	−	+	−	+	+	−	−	+	c^vDE/cde
	2nd son	−	−	+	−	+	−	−	−	−	−	−	*cde/cde*
C^u donor		+	−	+	−	+	−	−	−	−	+	+	C^uDe/cde

In a search for further allelomorphs at this locus, 284 blood samples were tested with three anti-C sera, as well as with anti-D, -E, -e, -c and -C^w. Two bloods gave discrepant reactions with the anti-C sera; they were therefore more fully investigated and provided evidence of the existence of two more allelomorphs at this locus, which we propose to call c^v and C^u.

The agglutination reactions of the blood of the c^v donor and of his family are shown in the table. The table also shows the reactions of the C^u blood; the family of this donor was not available, and therefore the evidence for the existence of the fifth allelomorph, C^u, is somewhat incomplete.

The reactions given by the blood of the c^v donor and of his father were identical. The fortunate fact that the younger brother of the donor was *cde/cde* demonstrated clearly the exact genotype of each member of the family. The allelomorph c^v was segregating with D and E genes, and it was the partnership of these three genes on one chromosome that suggested that, in spite of the agglutination of the c^vc bloods by three out of six anti-C sera, the use of a small c was the more appropriate notation; for *cDE* is a common chromosome in England and *CDE* an extremely rare one. Strong support for this choice of notation was provided in the finding that the blood of both father and son gave a double-dose effect with the three anti-c sera available.

The anti-c^v component in the three anti-$C + c^v$ sera must have arisen in response to stimulation by the antigen C; the gene c^v is much too rare to have played a part in the three immunizations. The two components of an anti-$C + c^v$ serum have not been separated. When such a serum is absorbed by either c^vc cells or Cc cells, all agglutinin is removed. Similarly absorption of anti-$C + C^w$ sera by C^wc or by Cc cells results in the removal of both components. It is probable that in such natural mixtures the antibodies may be on the same molecule. If an artificial mixture is made by adding pure anti-C^w to pure anti-C serum, the separation of the antibodies by absorption with C^wc or Cc cells is specific.



It will be seen from the diagram that it is possible to represent the interactions of the allelomorphic antigens with the antisera in such a way that the positive reactions of the latter show as uninterrupted lines. We do not yet know whether this is a chance occurrence; if it is of significance, it seems to impose a definite linear order, in one dimension, on the allelomorphs. At least it is clear that the allelomorph c^v bridges the gap between C and c.

A more detailed account of this work will be published elsewhere.

We wish to thank Dr. J. Loutit and the members of his staff at the National Blood Transfusion Service, Sutton, for supplying us with the 284 blood samples.

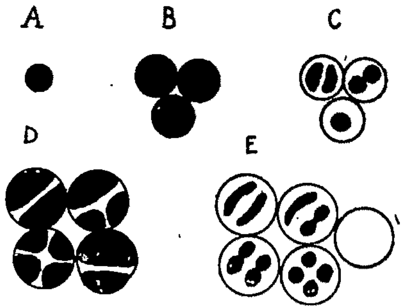
Cytology of Staphylococci Before and After Treatment with Penicillin

In a previous communication[1], we showed that, by means of enzymes, it is possible to localize both the nucleic acids of bacteria: (1) ribonucleic acid in the cytoplasm, (2) desoxyribonucleic acid in the nucleus. Thus, we have found a method, which seems to be general, of demonstrating the nuclei of bacteria. This method has enabled us to observe the nuclei, already known to exist, of the bacteria of the enteric and the anthracis-subtilis group and to discover the nuclei of bacillus diphtheria, gonococci and staphylococci. We have continued our investigations which enabled us to demonstrate the nuclei of meningococci, streptococci and pneumococci. In our first group, the staphylococcus was most difficult to investigate, and we were able to show its nucleus only by treatment with an alkali (lithium carbonate) previous to the action of ribonuclease ; but it was not very suitable because only isolated nuclei remained. We have overcome this difficulty by using higher concentrations of ribonuclease. It appears now that the method with ribonuclease, without previous alkaline treatment, has a quite general significance ; but for each micro-organism it is necessary to study optimal conditions of ribonuclease concentration and duration of enzyme contact required to eliminate the whole content of cytoplasmic ribonucleic acid, while avoiding the non-specific lixiviation effect on the desoxyribonucleic acid of the nuclei due to long exposure to hot solutions.

As part of a general programme of research, we have investigated cytological variations of a staphylococcus strain (pyogenic *Staphylococcus aureus* isolated from a human boil), the bacteria having been cultivated either (1) on ordinary agar broth medium, or (2) on agar broth medium containing a sublethal concentration of penicillin (75 units per litre of medium for this bacterium) which delays growth without stopping it.



A. NORMAL STAPHYLOCOCCUS. GENERAL BASOPHILY. *B*. NORMAL STAPHYLOCOCCUS. NORMAL SWELLING DURING THE LAG PHASE. *C*. THE SAME, AFTER RIBONUCLEASE TREATMENT: NUCLEI. *D*. STAPHYLOCOCCUS TREATED WITH PENICILLIN. DEMONSTRATION OF THE BASOPHILIC MASSES. *E*. STAPHYLOCOCCUS TREATED WITH PENICILLIN, AFTER RIBONUCLEASE TREATMENT: NUCLEI. (ON THE RIGHT, EMPTY SHELL: CYTOLIZED CELL ?) (DRAWN FROM PHOTOMICROGRAPHS)

Staphylococci cultivated on agar broth medium without penicillin. During the lag phase, the bacteria swell without multiplying, and after two or three hours they are twice as large as before. With the usual stains, they are entirely basophilic (Fig. *B*) ; but ribonuclease treatment demonstrates a nuclear apparatus (Fig. *C*). Then, there is in each coccus either a central or paracentral round nucleus, or, generally, two round or kidney-shaped nuclei showing divisions ; rarely, three or four nuclei can be seen in the bacteria. After five or six hours, the lag phase comes to an end and the cocci multiply vigorously and regain their initial size. They have generally two or one nuclei.

Staphylococci on agar broth medium with penicillin. During the very first hours, the cocci keep their normal size, then they swell very much, so that their diameter is three or four times the initial diameter. Hypertrophic cocci are no longer entirely basophilic, and after treatment with the usual stains, two, three or four chromophilic masses, separated by clear areas, may be observed (Fig. *D*). Ribonuclease treatment discloses two to four or sometimes five round or kidney-shaped nuclei showing numerous divisions (Fig. *E*). It seems that one or two nuclei form the centre of each basophilic mass which has already been mentioned. Later, most of the cocci gradually regain their usual size, and multiplication begins. But basophilic masses are found in bacteria as long as the micro-organism lives on a medium containing penicillin. When bacteria which have grown on agar medium with penicillin are transplanted on agar medium without penicillin (or agar medium with penicillin plus penicillinase) they regain their initial cytology, are entirely basophilic and have generally no more than two or one nuclei, according to the age of cultivation.

Summarizing : (1) penicillin produces, with staphylococci, during the lag phase, an exaggerated swelling ; (2) it changes the bacterial cytology and elicits differentiation of chromophilic masses separated by clear areas, an appearance which is not observed in normal bacteria even when they are old ; (3) it interferes with multiplication by inhibiting cytoplasmic rather than nucleal divisions.

We are endeavouring to find out, by chemical means, the variations of desoxyribonucleic and ribonucleic acid content in bacteria treated with penicillin. The results of these experiments will be reported later ; but we assume that the basophilic masses which can be observed under the influence of penicillin owe the most important part of this chromatophily to ribonucleic acid. After staining bacteria with neutral red, Pratt and Dufrenoy[2] have recently published drawings of staphylococci treated with penicillin which are similar to ours before ribonuclease treatment. They think that basophilic masses should be considered as vacuoles fixing the dye. So far as we are concerned, we think that these masses are perinuclear cytoplasmic areas in which ribonucleic acid has been stored, as a result of bacterial 'ill-health' due to the antibiotic.

Subtilin C : an Antibiotic Concentrate from *Bacillus subtilis*

A CONSIDERABLE literature[1], dating back to 1897, has established the activity of *Bacillus subtilis* strains against a variety of bacteria as well as viruses. A limited amount of work has been done on the isolation of the active constituents of *B. subtilis* cultures, and although several concentrates with distinct properties have been described, no pure active compounds have yet been defined.

In recent publications[2] by members of the Northern and Western Regional Research Laboratories, United States Department of Agriculture and the University of California, extensive investigations on the production of the active antibiotic concentrate subtilin from two strains of *B. subtilis* (*A.T.C.C.* 6633, *N.R.R.L. B* 543 ; and *A.T.C.C.* 7080, *N.R.R.L.* 537) have been described, together with some of its properties. As part of this work has been duplicated here during the past eighteen months, the results of investigations to date are now recorded. A more detailed account will be given elsewhere.

Of the twenty strains of *B. subtilis* examined, the strain *A.T.C.C.* 6633 displayed greatest antibacterial activity, the metabolism solutions being adjusted to *p*H 2·5 and autoclaved at 114° C. for ten minutes. The active concentrate subtilin had been isolated from surface cultures of this strain by Jansen and Hirschmann[1]. We used quick-freeze dried cells grown in submerged culture with aerating agitation on a medium of corn-steep liquor and sucrose. It was found, after several trials with different solvents, dilute acids, and inorganic salts, that the active principle was most advantageously separated when the cells were disintegrated in alcoholic suspension with glass beads or autoclaved with 80 per cent aqueous alcohol. By the use of the latter procedure, followed by dilution of the alcoholic extract with adjustment of the *p*H to 2·3, an active concentrate, which we will term subtilin *C*, was obtained as an amorphous powder.

Subtilin *C* in high concentration (1/2,000) was inactive against the Gram-negative bacteria tested, but Gram-positive organisms were generally susceptible to high dilutions; acid-fast bacteria showed a range of sensitivity. The substance had no lytic effect on a variety of organisms. It diffused only with great difficulty.

Antibacterial activity was determined by serial dilution of solutions or fine suspensions of subtilin *C* which had been adjusted to *p*H 2·5 and autoclaved at 114° C. for 10 minutes.

	Highest dilution of subtilin *C* giving 50% inhibition of growth after 24 hr. at 37 C. in glucose broth
Sarcina lutea	1/10,000,000
Staphylococcus aureus (6 strains)	1/80,000–1/8,000,000
Corynebacterium xerosis	1/5,000,000
Lactobacillus helveticus	1/2,400,000
Micrococcus conglomeratus	1/600,000
Mycobacterium from butter	1/300,000
Mycobacterium phlei	1/60,000

Complete inhibition of growth was given by two to four times the amounts of subtilin *C* required for 50 per cent inhibition.

Subtilin *C* is stable under certain conditions. A preparation stored for five months at room temperature in a desiccator in the dark showed no loss of activity. In solution in glucose broth, *p*-aminobenzoic acid (200 μgm./ml.), nicotinic acid, pantothenic acid and riboflavin (5 μgm./ml.), aneurin and pyridoxin (2 μgm./ml.), biotin (0·1 μgm./ml.), folic acid (0·01 μgm./ml.), 2 per cent casein hydrolysate, and asparagine and tryptophane (0·1 per cent), exerted no antagonistic effect in the concentrations given. The same was true of solutions of sodium chloride (2 per cent), glucose (2 per cent) and cysteine (0·04 per cent).

Under some conditions, the antibacterial properties of subtilin *C* were impaired. Exposure to sunlight for two days reduced the activity to 10 per cent of darkened controls at various *p*H values. With serum the results were not clearly defined. Using *Staph. aureus* as test organism, no significant loss in activity was observed over short periods (24 hr.), but contact for three days reduced the activity to 25 per cent of the original. Seitz filtration of a solution of the antibiotic resulted in loss of activity. Studies on the stability of solutions at various *p*H values showed that subtilin *C* was most stable at *p*H 2·5. It is rapidly destroyed in alkaline solution.

The properties of subtilin *C* would support the view that the active principle is a polypeptide. Hydrolysis by trypsin and pepsin resulted in loss of activity. It gave a strong ninhydrin reaction for α-amino-acids and positive tests with Ehrlich's reagent for indole derivatives and the Folin–Denis reagent for phenols. No coloration developed on treatment of an alcoholic solution with ferric chloride; this differs from the results obtained by the American workers.

I am indebted to Dr. F. Bergel and Prof. A. R. Todd for helpful suggestions and a continued interest in this work; also the assistance of Dr. Klein, Dr. Moss and Miss Ward in the microbiological work is gratefully acknowledged.

Serological Position of *Streptococcus bovis*

Streptococcus bovis, a conspicuous streptococcus of cow dung and also occurring in human fæces, has proved difficult to classify. Biochemically it is a well-defined species (Orla Jensen), and although it has some of the characteristics of Lancefield's Group *D* streptococci, its serological identity has long been obscure because of its failure to yield a group serum. While many strains of *Str. bovis* reacted with Group *D* sera, a not inconsiderable proportion gave negative or equivocal results[1,2,3], and until group sera for *Str. bovis* could be prepared its serological placing was necessarily left in abeyance.

Using an improved method of extraction, it has now been shown that virtually all strains are precipitated with a Group *D* serum. Moreover, by further improvement in the method of preparation of suspensions for inoculation, it has been possible to produce group specific sera from *Str. bovis* itself. Reciprocal absorptions with these sera and with sera prepared from other authentic Group *D* strains confirm that *Str. bovis* now takes its place with the enterococci as a member of Group *D*.

Intravenous Methylene Blue: a New Method for Studying the Nervous System

In 1886, Ehrlich[1] obtained striking results by the use of methylene blue as a stain for the nervous system. Of the many methods since developed for utilizing the staining properties of methylene blue perhaps the simplest and most reliable is the local injection technique of Weddell *et al.*[2]. The two main disadvantages of this method are the inevitable distortion of the tissue by the direct injection of the staining fluid and the limitation of the size of the region stained. Both objections may be overcome by continuously perfusing methylene blue into the veins of a living animal, conditions being so arranged that the animal survives for an extended period. The details of the technique are being published in full elsewhere[3], but the results obtained are so consistent that it was felt worth while to point out some of the possibilities of the method.

There appears to be no serious restriction on the number or type of tissues which can be studied in this manner, and the application of the method has already made possible detailed investigations on the pattern of innervation in striated muscle, blood-vessels (Millen[4]), and the cornea.

Fine morphological details may also be demonstrated, both in the peripheral and central nervous system. Thus, complicated end-organs such as muscle spindles stain with remarkable clarity, and a most striking feature is the demonstration of *boutons terminaux* in the central nervous system. *Boutons* have been observed in regions, such as the cerebral cortex, where they have previously been stained only with great difficulty or not at all.

There are many physiological problems to which this type of study might with advantage be applied. To take but one example, it should be possible, in cases of experimental poliomyelitis, to obtain a correlation between the condition of the affected muscles and that of the central nervous system in the same animal. For these reasons it appears that the method possesses considerable potentialities, in that it renders possible integrative studies of the functional anatomy of the nervous system.

Influence of Low Bicarbonate Concentrations on the Growth of a Green Alga

THE role of bicarbonate ions as a source of carbon for aquatic plants has been a subject of discussion for a long time. Steemann Nielsen[1] has recently given a short history of this question and published experiments showing that *Myriophyllum* has a greater ability than *Fontinalis* to use carbon from bicarbonate.

My own experiments have been made with a planktonic Green Alga, *Scenedesmus quadricauda* (Turp.) Bréb., and show that its behaviour is rather different from that of higher plants. The culture conditions of the inoculating material were the same as previously described[2], except that half the sodium carbonate had been exchanged for an equivalent amount of potassium carbonate.

In the experiments the Algæ were cultured in Jena glass tubes with 10 ml. of solution in each. The cultures were aerated with air (0·03 per cent carbon dioxide), or a mixture of 5 per cent carbon dioxide and 95 per cent air. The nutrient solution contained the same constituents as the solution for growing the inoculating material except that the carbonates were exchanged for equivalent amounts of disodium and dipotassium hydrogen phosphate, thus giving the solution a buffer of 1/44 *M* phosphate. The *p*H was regulated by adding various amounts of hydrochloric acid. After inoculation, the gas mixture that was used was blown through the cultures in the dark until the pressure of carbon dioxide in the solution was the same as in the gas mixture, that is, until the *p*H had a constant value. Usually four hours was enough. The cultures were then illuminated for ten hours. Four parallels were run, one of which was used up for *p*H determination at the beginning of the growth period, so that the growth determinations were made on three tubes the mean values of which are given in the accompanying figures. Growth was measured photometrically.

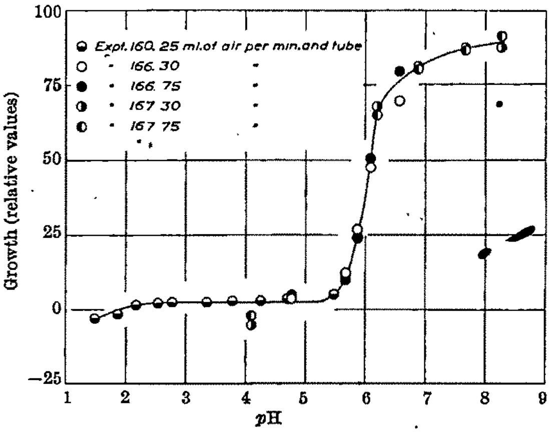

Fig. 1. GROWTH OF *Scenedesmus quadricauda* AT VARIOUS *p*H-VALUES IN CULTURES AERATED WITH AIR

When air is blown through the cultures, we get the curve of Fig. 1. Three experiments have been combined to form it because it was technically impossible to get all the points from one experiment. In two of the experiments two different rates of aeration have been used, and they show no difference. Another experiment has shown that carbon dioxide is taken up so rapidly from the air that, with the density of population used, the solution is practically in equilibrium with the air all the time. If a larger amount of inoculating material is used, this is no longer the case, and then the *p*H rises during illumination and falls to the original value in the dark if the aeration is continued.

The curve (Fig. 1) shows that growth is low between *p*H 2 and 5·5. Between *p*H 5·5 and 6·2 the curve rises very rapidly and continues to *p*H 8·2, which is the highest obtainable *p*H-value with this solution. In other experiments, not reported here, carbonate buffers have been used; and it is then possible to make growth determinations up to *p*H 9·8. The curve from this experiment shows an optimum at about *p*H 9 to which the 100 per cent in Fig. 1 refers.

The rapid rise in growth between *p*H 5·5 and 6·2 is not a direct effect of the acidity, for if 5 per cent carbon dioxide is blown through the cultures, growth is good even at *p*H 3–4.

I think the cause is to be found in the concentration of bicarbonate ions. In Fig. 2 we see the critical points of Fig. 1 placed in a graph where the abscissæ are the concentrations of bicarbonate ions, calculated from known constants. The growth is directly proportional to the concentration of bicarbonate between 1·5 and 9 μmol./l.

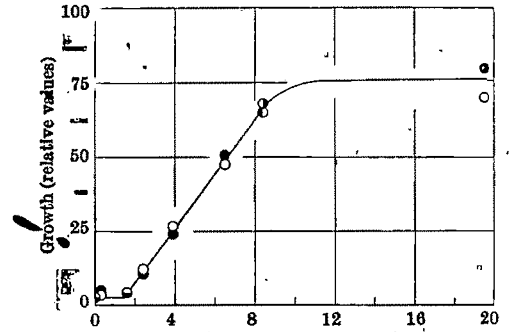

Fig. 2. GROWTH OF *Scenedesmus quadricauda* AT VARIOUS CONCENTRATIONS OF BICARBONATE IONS

The slight growth below 1·5 μmol./l. must be ascribed to the free carbon dioxide or carbonic acid, the concentration of which is 10 μmol./l. at all *p*H-values. A strange fact is that bicarbonate in concentrations below 1·5 μmol./l. was not assimilated. At bicarbonate concentrations greater than 9 μmol./l., growth is no longer limited by this substance but by other factors.

Steemann Nielsen (*loc. cit.*) has found that *Myriophyllum* and *Fontinalis* use carbon dioxide more rapidly than bicarbonate ions. In the case of *Scenedesmus*, we see that in a carbon dioxide concentration of 10 μmol./l., growth is very small; but in the same concentration of bicarbonate ion the growth amounts to 75 per cent of the optimal growth. Thus we see that various plants behave very differently with regard to the carbon source: *Fontinalis* assimilates about ten times better in carbon dioxide than in bicarbonate, and *Myriophyllum* two to five times better; but *Scenedesmus* grows twenty-five times better in bicarbonate than in carbon dioxide.

From Steemann Nielsen's curves one can see that the ability to use carbon dioxide is about the same for *Myriophyllum* and *Fontinalis*. The assimilation at 10 μmol./l. of carbon dioxide is very slow; and this is also the case with *Scenedesmus*. The differences are to be found instead in the ability to use bicarbonate. *Fontinalis* has a very slow assimilation in 10 mmol. of bicarbonate per litre, the assimilation of *Myriophyllum* amounts to 50 per cent of the optimal at 1 mmol./l., and *Scenedesmus* has 75 per cent of its optimal growth at 0·01 mmol./l.

It is very probable that these facts affect the distribution of the plants in lakes.

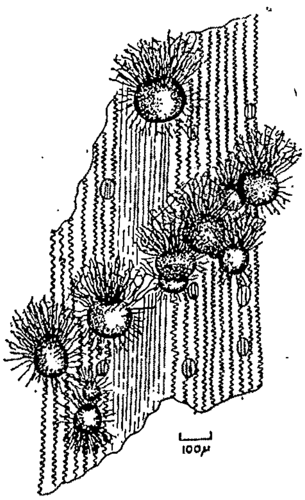
A *Chætomium*-like Thermophile Fungus

AMONG the various organisms which have been isolated at this Station from fermenting straw composts, one, *M.R.A.* No. 112, is of special interest. It is a thermophile Ascomycete producing perithecia which in many respects resemble those of the genus *Chætomium*.

Between the temperatures 40° C. and 50° C., on slopes of 3 per cent malt extract agar, *p*H 5·5, in a saturated atmosphere, vegetative growth is most luxuriant and perithecia are most abundant and most fertile. At 45° C. a small amount of mycelium deposited about the centre of a slope 7 cm. × 1·5 cm. spreads over the whole surface, often within the first twenty-four hours; procarpal structures and perithecial initials are well developed within thirty to sixty hours, and many fully formed perithecia containing ascogenous structures, asci or even liberated spores are to be found within ninety-six hours.



PERITHECIA OF THERMOPHILE FUNGUS, *M.R.A.* NO. 112, ON PIECE OF STRAW, APPROX. × 40 (SEMI-DIAGRAMMATIC)

Below 37° C. and above 55° C., growth on 3 per cent malt extract agar slows down markedly and ceases between 25° and 26° C. and between 61° and 62° C.

This remarkable fungus, which is probably a new species, surely holds the high-temperature record for vegetative growth and production of perithecia among Ascomycetes. Its taxonomic position is still under consideration; but as soon as this has been decided, further data, including descriptive details, will be published.

Treatment of Apple Canker Lesions with Plant-growth Substances

GIVEN that the formation and spread of a canker depends on the balance between the growth of the pathogen and the regeneration of the host, a substance which stimulates wound healing may prove as effective in combating the disease as one which aims at suppressing the pathogen. A number of the chemicals known as plant-growth substances stimulate callus formation, and it is possible that some of these may also suppress the development of the pathogen.

The effect of a number of growth substances on *Nectria galligena* Bres., the cause of apple canker, has been examined. In the first method used, records were made of the growth of the fungus on 2 per cent malt agar (*p*H 4·8) to which had been added 100 p.p.m. of the substance. It was found that during the greater part of the growth the increase in diameter was constant, and it was therefore possible to calculate a coefficient of linear regression of diameter on time which gave a fair estimate of the average growth-rate. Secondly, the effect of these substances on the growth of the fungus in liquid culture was observed by comparing dry weights of colonies grown in nutrient solutions containing varying concentrations of the substances in question. None of the substances used was strongly fungicidal and, although the more toxic produced a marked reduction in growth in relatively small concentrations, growth was not completely inhibited at very much higher concentrations. It was therefore found convenient to record as the toxic concentration the quantity required to reduce growth to less than 5 per cent of the controls. As the toxicity of these compounds is increased with increasing acidity, it is necessary to state the *p*H of the medium when quoting toxicity figures. The results of the tests described above are shown in the accompanying table, in which the second column relates to the tests on agar and the third column is derived from the results obtained in nutrient solution.

EFFECT OF PLANT-GROWTH SUBSTANCES ON THE GROWTH OF *N. galligena*

Substance	Growth-rate (mm. per day)	Toxic conc. in p.p.m. (*p*H 3·8)
2,4,6-Trichlorophenoxyacetic acid	1·22 (± 0·07)	40
1-Chloro-2-naphthoxyacetic acid*	1·07 (± 0·02)	40
α-Naphthaleneacetic acid	1·40 (± 0·05)	20
β-Indolylbutyric acid	2·37 (± 0·11)	60
β-Indolylacetic acid	2·59 (± 0·04)	100
β-Naphthoxyacetic acid	2·67 (± 0·16)	60
2,4-Dichlorophenoxyacetic acid	2·20 (± 0·09)	80
Control	3·01 (± 0·09)	

* Supplied by F. E. Smith, of Pal Chemicals, Ltd.

In preliminary field trials these substances were applied to established cankers at a strength of 1 per cent in lanoline; the cankers treated with β-indolylbutyric acid showed a marked improvement over the controls, but the others showed little difference.

These failures may possibly be due to the use of concentrations which were high enough to be toxic to the host.

I am grateful to Dr. L. C. Luckwill and to Mr. R. W. Marsh for their advice during the course of this work.

A New Dry Test for Gold

DURING the course of a systematic investigation of the mechanism of the blue mantle test for tin[1], it has been recently observed in these Laboratories that gold shows a similar reaction, but the colour of the mantle is a brilliant green.

The following procedure is adopted. Add to the gold salt in a porcelain dish a quantity of concentrated hydrochloric acid. Add a speck of metallic zinc and immediately dip a test tube, full of water, in the solution over the point where the hydrogen is bubbling up. On holding the test tube in the hottest portion of a Bunsen flame, a brilliant green mantle forms around the bottom of the test tube. The test is sensitive to 0·1 mgm. of gold per c.c. of concentrated hydrochloric acid. The presence of tin, however, interferes, and the green mantle is replaced by the characteristic blue mantle of tin. Copper also interferes.

As mercury, lead, silver and even platinum ions do not interfere, gold can be easily detected in a tin-free ore or alloy by dissolving the nitric acid insoluble portion in *aqua regia* and then applying the above test.

The mechanism of the test is not known.

Demonstration of the Heart Beat

THE explanation of Dr. C. A. Beevers' observations[1] (which I can confirm and to which I would add the further observation that the puffs of smoke correspond to cardiac systole) would seem to lie in the close resemblance of the human chest to the box used for the production of smoke rings to which he refers. Both have relatively rigid walls with a diaphragm and an orifice. In the case of the chest the contraction of the heart muscle during systole, acting from the relatively fixed great vessels of the head and arms, pulls its diaphragmatic attachment upwards, thus reducing the volume of the thorax. Air, being the most easily displaced thoracic content, is expelled in small jets corresponding to each cardiac systole and produces the effect noted by Beevers.

That it is not brought about by arterial pulsation in the mouth is certain because, during the process of blowing smoke from the mouth, the latter is in free communication with the lower air passages, and the comparatively small effect of local vascular changes would be lost in the very much greater volume of air (approximately 3 litres) present in the lungs and respiratory passages.

A possible additional cause is the throwing during each systole of upwards of 60 ml. of blood into the pulmonary circulation with displacement of air from the alveoli as the pulmonary capillaries dilate. This, however, is likely to be a much more gradual process and to be delayed for a considerable interval after systole.

Changes in the volume of the heart itself during the cardiac cycle might be thought to play a part; but consideration will show that any expulsion of air would be diastolic in time and also more gradual than a similar effect accompanying systole, being dependent on the flow of blood into the thorax via the superior and inferior venæ cavæ rather than its sudden expulsion from the heart.

It is doubtful if the accurate measurement of these pressure changes suggested by Dr. Beevers would provide any more valuable evidence of the condition of blood vessels than can at present be obtained by direct observations on an artery, as with various forms of sphygmograph, or on the volume changes in a limb with a plethysmograph.

ON looking further into the literature, I find that the 'cardio-pneumatic movement' has been described many times previously. For example, Haycroft and Edie (*J. Physiol.*, 12, 426; 1891) quote C. Voight as having recorded the phenomenon in 1865. However, these workers seem to have used a glass tube inserted into the mouth with a drawn-out portion in which the movements of the smoke particles are observed.

C. A. BEEVERS

INTERNATIONAL MEETING ON ANIMAL PRODUCTION

By I. L. MASON

Assistant Director, Commonwealth Bureau of Animal Breeding and Genetics, Edinburgh

A MEETING, sponsored by the Swiss Zootechnical Society, was held in Zurich during October 8–9, 1947, in order to renew professional and personal contacts severed by the War and to discuss the proposed formation of an International Society of Zootechny (or Animal Production). It was organised by Dr. W. Engeler, secretary of the Swiss society, and great credit is due to him and his colleagues for arranging the meeting at such short notice.

There were about 250 participants from twenty-six countries, and eighteen of these countries were represented by official Government delegates. Apparently the only delegate from outside Europe was Dr. Riddell, the United States agricultural attaché at The Hague, who was the official American representative. The only visitors from Great Britain were Mr. Alec Hobson (secretary of the Royal Agricultural Society of England and also representing the British Society of Animal Production), Mr. and Mrs. Gerald Strutt (Royal Agricultural Society of England), and Mr. and Mrs. I. L. Mason.

At the opening ceremony addresses of welcome were given by representatives of the Federal Department of Agriculture, the Swiss Zootechnical Society, the Swiss Breeders' Federation, and the Federal Technical College, where the meetings were held. All the speakers recalled with pleasure the International Conference on Animal Breeding held in Zurich in 1939, and hoped that the work interrupted by the War could now be continued.

At the first technical session, Dr. I. Moskovits, head of the animal husbandry section of the Temporary European Bureau of the Food and Agriculture Organisation, Rome, gave an exhaustive account of the international livestock situation, with particular reference to changes in livestock numbers, country by country, during the War, and Dr. A. Kiener presented a vivid picture of the Swiss livestock industry. It was very interesting to observe that the War had had much the same effects on livestock production policy in Switzerland as in Britain, namely, sharp reduction in pig and poultry stocks, owing to absence of imported feeding-stuffs, and emphasis on milk rather than on meat production.

On the second day of the meeting, official reports on the state of animal breeding in the following European countries were circulated: Austria, Belgium, Denmark, Finland, France and the Netherlands. In addition, Dr. Riddell and Prof. Csukás gave verbal accounts of animal breeding in the United States and Hungary respectively. Dr. H. Aersoe spoke on bull testing in Denmark; this information is already available in published form (*226. Beretning fra Forsøgslaboratoriet*, Copenhagen, 1947). In the discussion, Dr. Rijssenbeek (Netherlands) criticized the absence of daughter/dam comparisons and the restriction of the test to autumn calves. Dr. Horn (Hungary) pointed out the difficulty of comparing one year with another in a Continental climate; his observations also showed that some bulls might raise the annual yield, but depress the life-time production of daughters compared with dams. Dr. Rijssenbeek read a paper entitled "Horse-Breeding in the Netherlands"; it included an account of an apparatus for measuring the pulling power of horses, designed by Prof. Visser.

The rest of the day was devoted to the proposed International Society of Animal Production. The discussion was based on the provisional statutes drawn-up by the 1939 meeting. Those most desirous of forming the Society were Dr. Rijssenbeek, Dr. Engeler and Prof. Leroy (France). It was finally decided: (1) that an International Society of Animal Production should be formed on a Continental basis; the Continental sections could later link to form a world association; (2) that the society should be private and not governmental, and should be based on the zootechnical societies of each country; these societies include scientific workers, breeders, and administrators; (3) that a preparatory committee should be formed by representatives of the national zootechnical societies in Belgium, Denmark, France, Hungary, Netherlands, Switzerland and the United Kingdom; (4) that the secretariat should be at the Food and Agriculture Organisation Bureau in Rome, and Dr. Moskovits would be responsible for convening the committee; (5) that the committee should prepare a draft constitution and report at the next International Meeting on Animal Production, to be held in Paris in 1949. The preparatory committee would also prepare the agenda for the next conference. Dr. Moskovits suggested that the projected International Society might help to co-ordinate the research programmes in the smaller countries. At the moment, too many small experiment stations are attempting too much for their resources and achieving too little. Mr. Hobson described the formation and objects of the British Society of Animal Production, and promised its co-operation.

The meeting was conveniently arranged to coincide with the sixteenth Swiss National Livestock Show. This is a big event, lasting for nearly a month, horses, small stock and cattle being shown in succession. Judging was done before the public was admitted, and the prize animals were periodically paraded round the ring. In this parade, however, the emphasis was on the breed rather than the individual, and attention was directed to the characteristics, distribution and performance of each. In this way we were able to see the famous improved breeds of Swiss goats—the Saanen, Toggenburg, Appenzell, and polled Chamois—as well as the horned Chamois, Grisons, Verzasca, and Valais Blackneck, representing the mountain types. Most of the pigs in the country are Improved Landschwein or Large White. Sheep are of less importance; we saw the White Swiss Alpine, Brown-headed Mutton (Oxford) and the Black-brown Mountain breeds.

Cattle are by far the most important livestock in Switzerland. Two breeds divide the country between them—the Swiss Brown in the east and the Simmental in the west. They were excellently presented at the show, and in view of the single- versus dual-purpose controversy in Great Britain, it was extremely interesting to see such good examples of functional *triple*-purpose animals. In presenting them, the emphasis was placed on the importance of maintaining a balance between the production of milk, work and meat.

Further opportunity of studying these animals was provided by the expeditions organised in connexion with the meeting. We went to Einsiedeln in Canton Schwyz, the place of origin not only of the Swiss Brown cattle, but also of the Swiss Confederation itself. We saw three herds of Simmental cattle in the

Emmental and Simmental. Finally, we inspected Jura (or Freiberg) horses in the neighbourhood of Delémont, in the Bernese Juras. This is the only native Swiss breed ; it is a light-draft type, developed during the last fifty years. Wherever we went we were warmly welcomed and most hospitably entertained.

The arrangements for the conference were excellent. It is all the more unfortunate that the currency restrictions which prevail at every frontier prevented many people attending the conference and reduced to a minimum the stay of many others. Voluminous literature was available about the Swiss breeds of livestock. More important, these books and brochures were not merely propaganda, but gave factual accounts of characteristics and performance of animals and of methods of breeding and herd book registration.

INSULATING MATERIALS AND METHODS FOR USE AT LOW TEMPERATURES

THE Low Temperature Group of the Physical Society at a meeting on December 18, 1947, discussed insulating materials for use at low temperatures.

Sir Alfred Egerton, in the course of his presidential address to the Group, referred to the fact that the heat transfer by radiation in vacuum-jacketed vessels is greater than that predicted from theoretical calculations based on emissivities obtained from the electrical conductivities, and mentioned that a copper surface reduced with hydrogen at 300° C. is a better reflector for heat waves than a polished surface.

Sir Alfred then described thermal conductivity determinations carried out under his and Prof. Newitt's direction by Dr. C. S. Chow at the Imperial College. The apparatus consisted of an inner cylinder maintained at low temperature by liquid oxygen and an outer cylinder which served both as a heater and a water flow-calorimeter ; the material under test being packed between. Thermocouples were located at various positions to give the temperature distribution. Some of the data obtained are quoted below. They are mean thermal conductivities for a cold-face temperature of −181° C. and a mean temperature of about −84° C.

Material	Description	Bulk density (gm./c.c.)	Thermal conductivity (gm. cal. cm./$cm.^2$ sec. °C.)
Granulated cork, baked	49·5% 10–20 mesh 50·5% through 20 mesh	0·101	0·000066
Vermiculite	10–14 mesh	0·216	0·000112
	4–10 mesh	0·144	0·000082

,, ,,		0·197	0·000062
Cotton waste	Tangled thread form	0·131	0·000092

In a contribution from the National Physical Laboratory, Dr. Ezer Griffiths and Mr. M. J. Hickman reviewed the physical properties of insulating materials which have to be taken into account in practice in addition to thermal conductivity. They are bulk density, specific heat, fire resistance, water absorption, water repellency, permeability to water vapour, mechanical strength and settlement under vibration. The procedures for measuring these properties were outlined. For measuring thermal conductivity over the range of temperature of interest in refrigeration work, the hot-plate method was adopted : the plate being fitted with a coplanar guard ring. For the measurement of thermal conductivity down to about −78° C., a box or cylinder method has been used, the box being made of the material under test. The cold-face temperature was maintained at a constant low temperature by the use of a block of solid carbon dioxide, and the rate of sublimation of the solid carbon dioxide afforded a measure of the heat flow into the box.

A few of the results obtained with the various forms of apparatus are summarized below :

Material	Bulk density (gm./c.c.)	Mean temperature (°C.)	Thermal conductivity (gm. cal. cm./$cm.^2$ sec. °C)
Expanded ebonite	0·086	−27	0·000067
Balsa wood ..	0·101	−27	0·000075
Baked slab cork ..	0·107	−27	0·000079
,, ,, ,, ..	0·160	−27	0·000082
Cellular polystyrene	0·08	0	0·00010
Cellular chlorinated rubber	0·11	0	0·000092
Corrugated cellulose acetate sheets superimposed		−2	0·00011
Kapok (cieba fibre)	0·016	0	0·000072
Slag wool (water repellent)	0·176	−8	0·000085
Bonded glass fibre	0·048	0	0·000080
Cellular glass (fine pored)	0·18	−2	0·00013
Cellular polyvinyl formal	0·06	10	0·000090
Cellular ebonite (synthetic rubber)	0·07	10	0·000080
Foamed glue	0·03	16	0·000085

Dr. A. M. Clark (British Oxygen Co.) stated that the energy required to compensate the leakage of a unit of heat into a system at liquid oxygen temperature is fifteen to twenty times as great as that required to compensate for the leakage of the same quantity of heat at −30° C. The efficiency of a vacuum at liquid air temperature is about fourteen times that of a 10-cm. layer of a material such as baked slab cork. The complexity of the arrangement of a large industrial low-temperature plant, however, renders vacuum insulation impracticable to any great extent. He stated that the largest vacuum-insulated tank yet made for the storage of liquid oxygen had a capacity of 57 tons and an evaporation loss of 0·16 per cent of its contents per 24 hours. The largest storage vessel insulated with rock wool had an evaporation loss on the same basis of 0·2 per cent.

Sir Alfred Egerton stated that a vacuum-jacketed vessel of 30 gallons capacity for the storage of liquid methane had a rate of loss of 1½ gallons per 24 hours.

Dr. P. M. Schuftan (Gas Separation Branch, British Oxygen Co.) gave figures to show that the effect of improved insulation in oxygen plants was rather smaller than expected. For example, in an oxygen storage tank of 300,000 $ft.^3$ capacity fitted with the usual magnesia insulation, about 3 per cent of the product is gasified by heat influx from outside. This amount of gas can, as a rule, be fully utilized for cylinder filling and only the latent heat of the oxygen is lost, adding about 2 per cent to power consumption and 1 per cent to total operating costs.

Prof. F. E. Simon discussed the process of heat conduction in solids, emphasizing the role of the mean free path of the heat waves. Reduction of the mean free path by disturbing the lattice, either physically (mechanical distortion, use of super-cooled disordered phases) or chemically (alloying), gave a very low thermal conductivity at low temperatures.

In the subsequent general discussion, stress was laid on the possibilities of an insulator composed of powder or fibres with gas at low pressures in the interspaces.

EZER GRIFFITHS

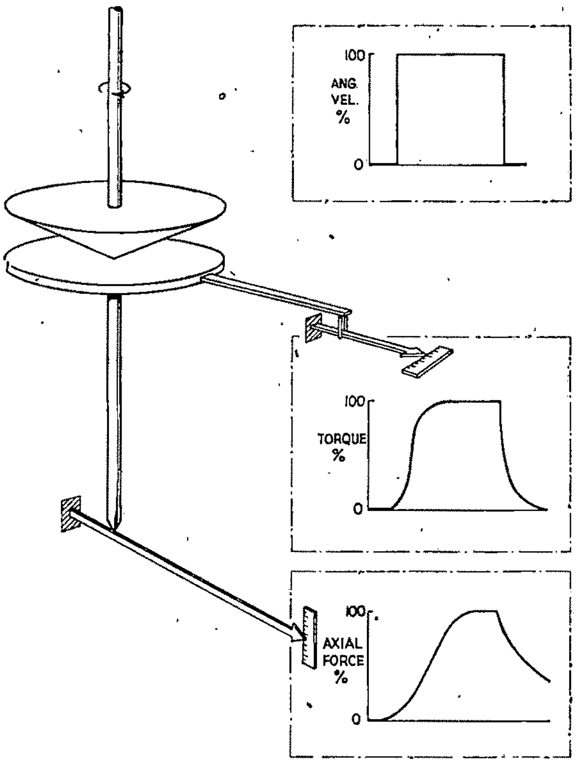
SOME NEW ANISOTROPIC TIME EFFECTS IN RHEOLOGY

By S. M. FREEMAN and K. WEISSENBERG
British Cotton Industry Research Association,
Didsbury, Manchester

IN rheology we study the development in space and time of the *mechanical variables*, that is, of the stresses and strains which co-exist in a material in every differential cell, and at every instant. Our concern here will be the comparison between different directions in space, and we shall speak with respect to any quantity, or development, of *isotropic* symmetry to denote identity in the various directions, and of *anisotropic* symmetry to denote differences from one direction to another.

Let a material be observed as it passes under some mechanical action through a series of rheological states, and let all such states be divided into *sheared* and *shear-free* states according as we can, or can not, find a tangential component of the mechanical variable under consideration on a plane of at least one orientation. It can then be shown that any passage between a shear-free and a sheared state will necessarily exhibit some anisotropic development in time, even if the material itself is of the isotropic kind, that is, shows the same response to mechanical actions in all directions of space when tested in a *ground-state*, where it is at rest and free from externally applied forces. (It follows from symmetry considerations that every shear-free state must be isotropic, and every sheared state anisotropic; and hence, any passage between the states of the two classes must exhibit anisotropic time effects with respect to the mechanical variable which possesses a tangential component.) We shall restrict our attention here to such isotropic materials, subjected to laminar shearing displacements. The laminæ which glide over one another will then suffer tangential and normal components of stress which—according to the theory[1]—must vary simultaneously at differing percentage rates, showing, for example, different exponential indices during an exponential build up, or relaxation. In general, when the tangential component varies as an odd function of time, the normal one must simultaneously vary according to an even function, so that under vibrational displacements in which the former varies with some frequency around a mean value of zero and according to a sine function, the latter must vary simultaneously with double that frequency around a mean value different from zero, and according to a cosine function.

The experiments were actually made on isotropic materials of the visco-elastic type, such as liquid and solid colloids containing rubber, saponified oils, pastes of starch, cellulose acetate, etc., because this type exhibits the anisotropic time effects in an easily accessible range of mechanical actions. (Liquids are understood here as materials which flow under any shearing stress, however small; while solids are capable of maintaining such stresses statically up to a certain limit.) Further, the materials were so selected as to be sensibly incompressible (within the range of applied actions), as this brings about a simplification of the effects here considered.



The accompanying illustration shows on the left-hand side a schematic diagram of the apparatus, and on the right-hand side a typical set of experimental results. The apparatus used was a version of the rheogoniometer[2] specially designed to impose on a material laminar shearing displacements and to measure along various directions in space the development in time of the stresses. The framework of the apparatus consists of a watchmaker's precision lathe with its axis mounted in a vertical position. Concentric with this axis, and secured respectively in the head- and tail-stock of the lathe, are a circular cone (vertex downwards) and a plane circular disk, which touch one another, and form respectively the roof and the base of a horizontal gap of small height, containing the material under examination. One may impose on the material any laminar shearing displacement desired. For this the cone is rotated about its axis but held rigidly against axial translations, while the disk is kept sensibly at rest by constraints against both rotations and axial translations. The wedge-like shape of the gap then ensures that the material suffers the same amount of shear strain in every differential cell of the gap. The apparatus is equipped with measuring devices. For the strains the angle of rotation of the cone is measured and recorded as a function of time, while for the stresses it is necessary to register the action which the material exercises on the disk. To do this, the constraints of the disk are given the form of elastic cantilevers which yield immediately to the action and thereby measure, and record as functions of time, the *torque* and the *axial force*, that is, the moment about the axis, and the force perpendicular to the plane of the disk. As the yield of the cantilevers changes the dimensions of the gap, it is necessary to prevent these changes from becoming large enough to disturb the time effects significantly, and to use combinations of mechanical and optical lever systems (not shown in the figure) with a sensitivity of about 10^{-6} cm.

The experimental results are conveniently expressed by three graphs in which are plotted, against time, the angular velocity of the cone and the torque and axial force on the disk, each quantity being expressed in percentage of its maximum value. Assume the material to be incompressible, and the motion one of laminar shear throughout the gap. The torque, T, and the axial force, F, are then related to the stress components tangential and normal to the plane of the disk by a purely geometrical factor, and as this factor is independent of time, it cancels out when the percentage values are considered as functions of time. Explicitly, introducing cylindrical co-ordinates, we find that in a differential cell at a point (r, φ, z) the stress, P, has in the plane of the disk the tangential and normal components

$$P_{\varphi z} = P'_{\varphi z} \text{ and } P_{zz} = -P'_{\varphi\varphi} \log R/r,$$

whence integrating over the area of the disk we deduce

$$T = \tfrac{2}{3}\pi R^3 P'_{\varphi z} \text{ and } F = \frac{\pi}{2} R^2 P'_{\varphi\varphi},$$

where the indices attached to P indicate the co-ordinates involved and the dash denotes the value at a point of the rim of the gap $(r = R)$.

For such an ideal case the three graphs obtained for the macroscopic development in time must be identical with those obtained in every differential cell of the material for the percentages respectively of the strain velocity, and of the stress components tangential and normal to the plane of the disk. (The height of the gap is chosen sufficiently small to make the forces of inertia negligible under the motions of the material here considered.)

In one type of experiment we used visco-elastic liquids; solids are more troublesome for this type of experiments, since in the build-up period they tend to break under the large strains required, and in the relaxation period show inconveniently slow changes of stress. We were concerned with the time effects encountered in the build-up, and in the relaxation of the various components of stress during periods of stationary rates of laminar shearing displacements. It might appear that during these periods any liquid would run out of the gap. However, in the conditions of shear considered, the visco-elastic liquids used here develop hoop-stresses sufficiently strong to form a cylindrical free boundary, and prevent the running out. At first the material was in its ground-state, and the cone and disk were at rest. Next we started a period of build-up of stress by keeping the disk at rest and suddenly imparting to the cone a rotation with an angular velocity that was maintained throughout the period at a constant level sufficiently high to bring about measurable torques and axial forces on the disk. Finally we proceeded to a period of relaxation of stress by suddenly arresting the motion of the cone and keeping the cone and the disk at rest henceforth. Both periods were covered by a photographic record, and a typical set of results is shown on the right-hand side of the figure in the three graphs. The actions applied to the cone are seen in the graph of the angular velocity, and the anisotropic time effects in the differences between the graphs of the torque and axial force. Interpreting the graphs for every differential cell of the material, we find that the strain velocity is exactly synchronized with the action on the cone, while the stress components are delayed, and show anisotropic time effects, the percentage rates of build-up and relaxation being different as between the components tangential and normal to the plane of the disk.

In a second type of experiment we used visco-elastic materials, both liquid and solid, and proceeded as in the first type, except that the shearing displacement imposed by the rotation of the cone was now varied harmonically in time, with a frequency and amplitude chosen sufficiently high to give measurable torques and axial forces. The results obtained so far showed that, in this case, the torque, and the tangential component of stress, varied around a mean value of zero with the same frequency as the imposed displacement, while the axial force and the normal component varied around a mean value different from zero with twice that frequency. The phase and amplitude relations are still being investigated.

The experiments thus show that anisotropic time effects are produced even in isotropic materials during transitions between shear-free and sheared states, and that in the case of laminar shearing displacements the tangential and normal components of stress conform to the theory, showing simultaneously different times of build-up under a stationary rate of displacement, different times of relaxation under constantly maintained displacement, and different frequencies of vibrations under harmonically varying displacements.

The authors' thanks are due to the Director of Research at the Shirley Institute for the opportunity of performing this work and permission to publish it.

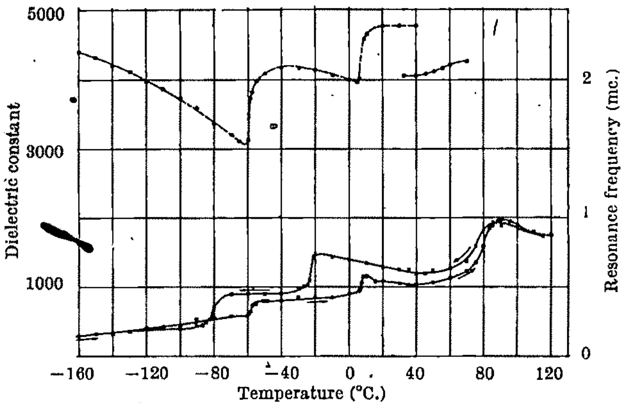
DIELECTRIC CONSTANT AND PIEZO-ELECTRIC RESONANCE OF BARIUM TITANATE CRYSTALS

By BERND T. MATTHIAS

Laboratory for Insulation Research, Massachusetts Institute of Technology

THE growth of barium titanate single crystals and the ferro-electric behaviour of their pseudocubic modification have been described earlier[1,2], and more detailed data can now be given.

There can be obtained at least four modifications of barium titanium compounds, among which the hexagonal and the pseudocubic ones definitely are stoichiometrically $BaTiO_3$[1,2,3]. The dielectric constant of the hexagonal modification is comparatively low, namely, between 100 and 200. The temperature characteristic shows two small peaks near 0° C. and 100° C., at which points maxima of the dielectric constant for the pseudocubic crystals have been found[3].

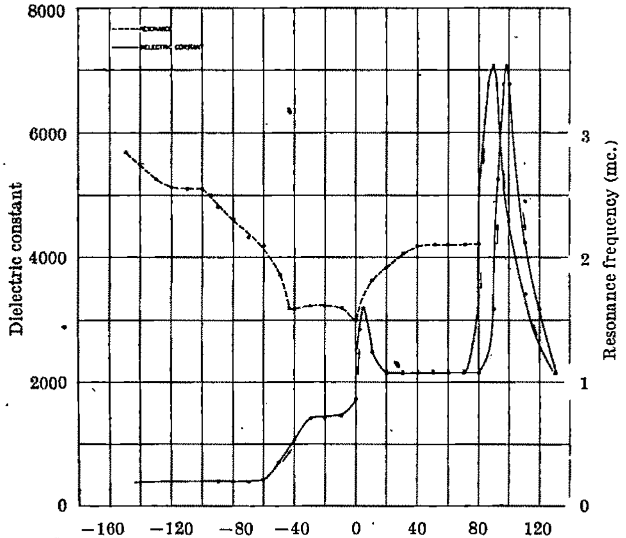


Barium titanate crystal (100)

Crystals of the pseudocubic modification grown from alkali carbonates or barium chloride show a discoloration which ranges from yellow to clear red. Spectroscopic investigation confirmed that this colour is mainly due to dissolved platinum. Colourless crystals were obtained by using carbon crucibles.

The dielectric constant and the piezo-electric resonance frequency have now been measured as a function of temperature, parallel to the three crystallographic directions of the *same* crystal, that is, along its cube edges. The electric field strength was less than 1 volt per cm. at a frequency of 1 kc. The Miller indices on the graphs serve merely to distinguish the three directions in which the electric field was applied to the cube. The crystals usually are twinned with respect to the 011 and 01$\bar{1}$ planes[4].

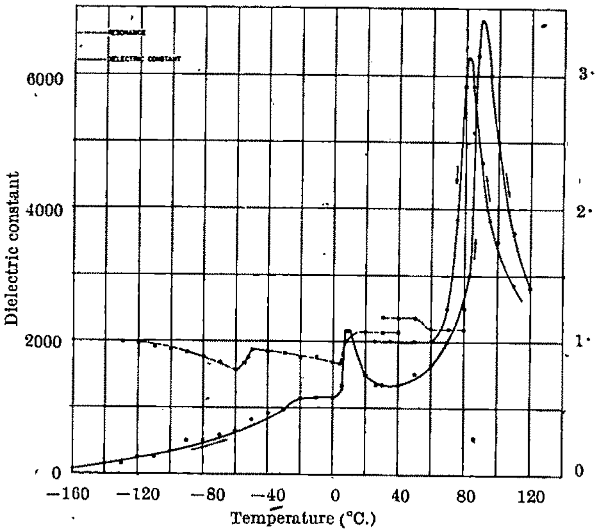
Dielectric hysteresis characteristics have been observed in all three directions and show that the hysteresis disappears only above 100° C. (Slight deviations in temperature from values observed by other authors are probably due to impurities.) Therefore, this temperature represents the only Curie point in contrast to the peaks around 5° C. and −70° C., as already shown in previous measurements[2,3,6]. The course of the piezo-electric resonance indicates some kind of a transition at these temperatures[5], but more investigation is necessary to reveal its nature.



Barium titanate crystal (001)

The thermal hysteresis is considerable and has to be attributed to the existence of large (about 1–2 mm.) spontaneously polarized domains, which are easily visible[7].

From the crystallographic point of view, the present situation is different from that of Rochelle salt or the di-hydrogenphosphates in that barium titanate is a new type of ferro-electric in which all the three crystallographic axes seem to show a similar behaviour. The twinning might give some erroneous results for the absolute value of the dielectric constant; but as microscopic observations with a heating stage show, the twinning should only affect the 010 and 001 results, since here the different axes might overlap one another. That there is virtually no twinning perpendicular to 100 confirms the fact that the ferro-electric behaviour of barium titanate is much less anisotropic than that of the above-named salts, and much more similar to the ferro-magnetics. Considerable progress has been made in obtaining untwinned crystals, and more conclusive results will be given shortly[7].



Barium titanate crystal (010)

Whether the crystals in the Curie range really are tetragonal seems doubtful. Observations with polarized light, made by Prof. Fairbairn of this Institute, give no evidence whatsoever for a tetragonal structure, but point to optical biaxiality. More complete optical data would be desirable and will be obtained when larger unstrained crystal sections become available.

From the dielectric and piezo-electric behaviour of single crystals given above, the peculiar piezo-electric property of barium titanate ceramics[8] may be perhaps interpreted similarly to the quadratic magnetostrictive effects in polycrystalline iron.

EXPLORATION OF THE LLOYD GEORGE MOUNTAINS IN THE NORTHERN CANADIAN ROCKIES

By Dr. N. E. ODELL

AN Anglo-Canadian-American expedition, sponsored by F. S. Smyth, and consisting of seven members, was able during the past summer (1947) to carry out the exploration of the Lloyd George Mountains, which are situated in northern British Columbia. This mountain group lies just south of lat. 58° N., and only the foothill district to the south of it had previously been visited. The name Lloyd George Mountains, in honour of the late British premier, was given in 1916 by P. L. Haworth, who made a difficult journey to the lake, now named after him. It was Haworth Lake, fed by the melt-waters draining the Lloyd George Icefield, which was utilized by this year's expedition as a base.

We were an airborne expedition, and flew in a sea-plane in two parties, from a take-off some 250 miles to the southward. A reconnaissance flight was made from Haworth Lake (altitude *c.* 3,800 ft.) before the departure of the aircraft, and this revealed a vast snowy range lying to the north-west as well as the south-east of the contiguous Lloyd George Group. It is a highly complicated and deeply dissected mountain region, with the highest peaks approaching 10,000 ft. in elevation. The eastward flowing Liard River, bounding this belt of mountains on the north, would seem to form the true northern limit of the Rocky Mountains proper, as originally suggested by R. G. McConnell and again recently by M. Y. Willams[1].

The dominating physiographic feature, from which rise the highest peaks, all of which were ascended, is the Lloyd George Icefield, and its main *névé* covers some 45 sq. miles, but with dependent glaciers it is 90–100 sq. miles in total extent. Steep glaciers descend to an altitude of 4,000 ft. in heavily forested valleys, which are the haunt of bear, deer and other game. A very rich and beautiful alpine flora was found, particularly in July, up to an elevation of 7,000 ft. and more. More than two hundred species were collected, some believed new, and these were sent for determination to the Royal Botanic Garden, Edinburgh. The flora was quite as profuse as hundreds of miles farther south in the Canadian Rockies.

As to the solid geology, the district explored lies entirely eastward of the Rocky Mountain Trench, that great structural feature which separates the Rocky Mountains proper from the diverse ranges of the central portions of British Columbia. The latter region is underlain by sedimentary and volcanic rocks of Palæozoic and Mesozoic age, with immense batholithic intrusions, ranging in age from pre-Carboniferous to Tertiary, and considered to have been the source of the metallic mineral deposits of central British Columbia.

In contrast, the ranges of the Rocky Mountains eastward of the Great Trench are a series of highly folded sediments with representatives of practically the whole geological succession, but without eruptive rocks, and devoid of ore deposits.

The Lloyd George Mountains are carved out of a great thickness of Palæozoic rocks, which are overfolded towards the east and often display in individual peaks the characteristic tilted fault-block type of structure and so-called 'writing desk' form, so prevalent elsewhere in the Canadian Rockies. Mainly composed of hard limestones, the softer interbedded shales and slates, with the softer limestone, are normally highly folded and sheared. No extensive overthrust masses (*nappes de recouvrement*) were observed. Compression and shear have been responsible for the destruction of almost all organic remains, and only in one locality high up in a mountain face was found a fossil coral horizon which appears to be of Silurian age. The field collection made by me has yet to be worked out.

Regarding the glacial geology, an outstanding discovery was a large stagnant glacier, lying in a deep canyon-like valley, which was entirely blanketed in moraine, and upon which trees and plants were growing. This glacier, extending through a range of altitudes of from 4,500 to 6,000 ft., appears to be the only one of its kind which is known south of Alaska.

The glaciers of the region generally appear to be in a state of slow recession. The present summer snow-line lies at approximately 7,900 ft.

The survey, and other scientific work of the Expedition, was greatly hampered by the prevailing bad weather, which, throughout the Rockies during the summer of 1947, was the worst on record for forty or more years.

CAMBRIDGE ARCHÆOLOGICAL EXPEDITION TO CYRENAICA

By C. B. M. McBURNEY, R. W. HEY and W. WATSON

THE first Cambridge Archæological Expedition to Cyrenaica, North Africa, took place during the summer of 1947. A total of three months was spent in the field, and the following were the principal results obtained.

The primary object of the expedition was to investigate the Palæolithic succession in the coastal area, and to correlate it, if possible, with any traces that might be found of a marine Pleistocene succession. Italian geological literature of the pre-war period mentions the presence of marine Pleistocene deposits in the Benghazi plain, and refers to probable Pleistocene shore-lines at several points along the Cyrenaican coast. So far as we know, however, no detailed study of these was ever undertaken.

Accordingly, the first part of our time was spent in an examination of the more accessible portions of the coast between Benghazi and Derna, in order to locate beach conglomerates, wave-cut terraces and other traces of high level shore-lines. These were discovered in fair abundance, though obscured in many places by masses of alluvial material. From the results obtained by levelling such features, it is hoped to establish the Pleistocene succession of sea-levels for this part of the coast. The highest shore-line of which traces were found was at some 80 metres, in the Derna region; the lowest lay at about 6 metres and was preserved in most of the areas examined. The intermediate levels are still under consideration.

The cultural succession associated with these events proved most instructive. Traces of the Middle Palæolithic could be recognized at various points along the coast, and a few specimens embedded in the beach conglomerates can probably also be attributed to the same stage. A rich Levallois station was discovered five miles west of Derna and can almost certainly be associated with the terra rossa at 5 metres above sea-level.

On the other hand, an evolved Mousterian industry occurred in a silt deposit in a tributary of the Wadi Derna, associated with a vertebrate fauna and well-preserved plant remains. This deposit interdigitates with the high terrace of the Wadi Derna, which was surveyed down-stream to a point about three-quarters of a mile from the sea. There is no doubt that this terrace was formed in connexion with a sea-level much higher than the present, though further work will be necessary before an exact estimate of the height of this level can be given.

No traces earlier than blade industries of Upper Palæolithic or later date occur on the consolidated dunes which line the modern shore, and which presumably belong to the low sea-level of the last glaciation.

Detailed information regarding the form and associated fauna of at least one phase of these later industries was obtained from a cave discovered and excavated in the Wadi Cuf, fifteen miles from the coast. The two faunas, and the flora from the Wadi Derna, should provide considerable information on the Pleistocene climatic sequence of the east Libyan seaboard.

We should like to express our gratitude for the assistance afforded by King's College, Cambridge, and the British Museum, in defraying the expenses of two of the members of the expedition, and particularly to the Trustees of the Percy Sladen Memorial Fund for their generous grant, without which the expedition would never have been undertaken. The constant help and co-operation of the authorities of the British Military Administration of Cyrenaica was also an important factor in the success of the expedition.

A further visit, in the near future, to amplify and complete these findings, is planned.

THE COMMON COLD

THE Cantor Lecture before the Royal Society of Arts, delivered on January 20 by Dr. C. H. Andrewes, of the National Institute for Medical Research, is an admirable summary of the essential features of our knowledge of that world-wide scourge, the common cold; and nobody is better fitted than Dr. Andrewes to state what we know and what we do not know about it. This problem is being attacked energetically by a research unit of the Medical Research Council in a hospital built at Salisbury during the War by Harvard Medical School and the American Red Cross, and eventually presented to the Ministry of Health.

If, as Dr. Andrewes showed, those who are working on this problem in Great Britain and other countries are only beginning to pick up clues to the solution of what is one of the most complex problems of virology, there is plenty of evidence that this relative ignorance will not persist for very long. All the portents, indeed, suggest that presently the common cold, like typhus, typhoid, cholera, smallpox, yellow fever and other plagues, will have yielded to human domination. But this will not come about without much patient research and, when that research has found the methods of control and cure, the co-operation of the public will be required. For, as Dr. Andrewes explained, the common cold, or more accurately, perhaps, the various varieties of it which probably exist, depend very much for their dissemination upon such human habits as sneezing, coughing, handkerchief-waving and so on—all of them habits which people will not readily alter to the degree that scientific control of infection requires.

The work of the Air-Hygiene Unit, the members of which are collaborating more and more closely with the workers on the common cold, demonstrates the importance of this aspect of the problem. It has been shown, for example, that handkerchiefs shaken in the air can disseminate very many bacteria, and other work suggests that impregnation of handkerchiefs with certain substances, among which phenyl mercuric bromide is promising, may make them less dangerous. Possibly the handling of infected handkerchiefs, rather than waving them about, may be an even more important means of dissemination of the organisms concerned.

Research on the common cold, like all work on diseases caused by viruses, was hampered until methods of cultivating viruses in the laboratory were discovered. Now that these are available, it is possible to use, for work on the common cold, the method of cultivation of viruses which has been more successful than any other, namely, their cultivation on the fertile hen's egg. American workers have claimed that they have successfully grown the 'cold' virus in hen's eggs; Dr. Andrewes and his colleagues, who are attacking the whole problem in Britain, have used the same techniques, but have so far been unable to confirm the American results. Dr. Andrewes discussed this point and suggested that probably the two groups of workers are studying colds due to different causes, the American type of cold being more like the condition known as sinusitis, whereas the British workers are studying the runny-nose type. Thus one of the important requirements is successful isolation and cultivation in the laboratory of the viruses concerned, of which there may be several.

Another great handicap in this work is the lack of a suitable experimental animal. The virus of human influenza will 'take' in ferrets, but the chimpanzee is the only animal so far known to be susceptible to the human common cold; and chimpanzees are expensive and difficult to handle. Human volunteers must therefore be used, and in his lecture Dr. Andrewes described the work being done at Salisbury where the Medical Research Council Unit has so far had the help of five hundred human volunteers. A sound technique has now been evolved; methods of storing and filtering the virus have been worked out; it has been shown that the incubation period of the colds studied was two to three days, and that the nasal secretions will not communicate a cold if they are diluted beyond 1 in 100. Bacteria-free filtrates of nasal washings from volunteers with colds have produced colds in about 50 per cent of subjects, and this has happened all the year round, with possibly a lower percentage of colds acquired during the winter.

This last point will surprise those who believe that cold and wet precipitate, or even cause, colds; but Dr. Andrewes made wise and salutary comments on this view in the section of his lecture devoted to the effect of the season and the weather, and in the interesting section on the incidence of colds in the Arctic and in Spitsbergen, where the outbreak of colds is intimately connected with the arrival and departure of ships from the outside world. This part of the lecture and also Dr. Andrewes' remarks on the value of the many cold cures that are constantly recommended should certainly be read by the "scores, perhaps hundreds" of people who have written to the Salisbury Unit to tell them how to solve this difficult problem.

Men of science will appreciate this lecture as an example of how to handle an intricate subject with a charm and simplicity of phrase which make it readily intelligible to everybody.

G. LAPAGE

BRITISH ROCKET WEAPONS RESEARCH

THERE is nobody better qualified to discuss our war-time development of rocket weapons than Sir Alwyn Crow, and it would therefore be unprofitable to attempt to dispute the clear statement of facts which he presented as the thirty-fourth Thomas Hawksley Lecture at the Institution of Mechanical Engineers on November 21, 1947, his subject being "The Rocket as a Weapon of War in the British Forces".

Sir Alwyn first traced the development begun in 1935 of the three main types of motor which formed the basis of almost all British rocket-propelled weapons. These were steel tubes of 2 in., 3 in. and 5 in. diameter containing a solid cordite propellant charge, which was ignited at the front, the gases being discharged in each case through a single nozzle at the rear. Pointing out that from the military point of view one of the greatest advantages of the rocket propulsion of missiles is the absence of recoil forces on the projector, Sir Alwyn went on to describe how these motors were combined with different types of explosive head and projection apparatus to meet such varied demands as for anti-aircraft fire, barrage weapons for mass bombardment and airborne projectiles for land and sea targets. He also described the development of rocket motors of the high degree of reliability necessary to provide the extra thrust which enabled aircraft to take off with a much shorter run. An idea of what was achieved in these fields may be gathered from the fact that "a single craft was able to fire highly lethal ammunition on the chosen target area at the rate of half a ton a minute for nearly a minute at a time", and the hitting power of a single aircraft was "momentarily the equivalent of the full firing power of a medium cruiser".

As this was his main concern, Sir Alwyn's paper dealt primarily with the detailed development of solid-fuelled rockets to meet a number of specific requirements; but since there can be little doubt that British progress in the field of rocket development at the end of the War was some ten years behind that of the Germans, it would be interesting if Sir Alwyn could be persuaded to present his views on a number of the other aspects of this type of armament, aspects which must have been the subject of much discussion because of their fundamental nature. Were difficulties of production and the impossibility of making the necessary research in the early stages the obstacles that precluded the use of liquid fuels, with the enhanced index of performance which would be expected from them? Why was so much greater emphasis placed on fin stabilization than on spin stabilization? Was progress made in the examination of methods of control and guidance of the projectile during its flight, or was it considered in Britain that the inherent advantages of the unguided weapon outweighed any which might accrue from guidance? Even our choice of solid propellants appears to have been very limited, and it would be interesting to know what attempts were made to develop other types. The use of light alloy tubing for the motor body would seem to be an obvious way to increase the charge/weight ratio, and the steps made to investigate its possibilities would be worth knowing.

The only fair criticism which can perhaps be made of Sir Alwyn's lecture is that he made no mention of the aiming and sighting equipment developed to ensure that the projectiles would arrive at the right spot at the right moment, for if they fail to do this all the ingenuity lavished on the design of the weapon is useless.

R. H. MACMILLAN

PHOTO-ELASTICITY IN MECHANICAL ENGINEERING

TWO papers which make a very useful addition to the sparse literature on photo-elasticity were presented to the Institution of Mechanical Engineers on December 12, 1947. Mr. W. A. P. Fisher's paper dealt with the basic physical properties of model materials which are relied upon in the 'frozen stress' technique of three-dimensional stress analysis. This technique, which was originated in Germany and the United States, is based on the fact that certain photo-elastic model materials have a very low Young's modulus at elevated temperatures and consequently suffer considerable deformations under small loads. If such small loads remain in position during subsequent cooling, it is found that the materials set in the strained position and retain, after the removal of the loads, virtually the whole of the strain and the photo-elastic effect associated with the loading at the elevated temperature; hence the term 'frozen stress'. This phenomenon is utilized in three-dimensional analysis by cutting thin slices from a three-dimensional model, which can then be examined in a photo-elastic polariscope in accordance with the ordinary two-dimensional technique. The 'frozen stress' patterns are not found to be appreciably disturbed by careful cutting.

The major part of Mr. Fisher's paper was devoted to a discussion of the suitability of phenol-formaldehyde resins, particularly 'Catalin 800', for use with this technique. In the United States, glyptal resins have been used for this purpose almost without exception; but as this material is very expensive and difficult to obtain in Britain, considerable interest is attached to the detailed investigation of the merits of 'Catalin' which was carried out at the Royal Aircraft Establishment, Farnborough, by Mr. Fisher. Data were given in the paper of the physical properties of 'Catalin', both at room temperature and at its softening temperature. Young's modulus at 80° C. appears to be about 1/120 of the value at room temperature. The paper also contained some practical illustrations of the 'freezing' technique.

Mr. R. B. Heywood's paper on "Some Modern Applications of Photo-elasticity" contained a brief outline of photo-elastic theory and a summary of the properties of the more important model materials, followed by some interesting examples of applications to design problems taken from the field of mechanical engineering.

It will be an encouragement to everyone interested in photo-elasticity that the engineering institutions are once more, after a long interval, taking an interest in this valuable method of stress analysis.

E. K. FRANKL

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, March 1

FARMERS' CLUB (at the Royal Empire Society, Craven Street, Strand, London, W.C.2), at 2.30 p.m.—Prof. G. E. Blackman: "Oil as a Farm Crop".

CHEMICAL SOCIETY, BIRMINGHAM SECTION (in the Chemistry Lecture Theatre, The University, Birmingham), at 4.30 p.m.—Prof. C. K. Ingold, F.R.S.: "Steric Hindrance".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 4.30 p.m.—Prof. Eric K. Rideal, F.R.S.: "Colloids". (Further lectures on March 8 and 15.) (Cantor Lectures.)

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (joint meeting with the LONDON SECTION of the INSTITUTE OF METALS, at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Mr. C. J. P. Ball: "The Manufacture and Usage of Magnesium and its Alloys".

ROYAL INSTITUTE OF CHEMISTRY, LONDON AND SOUTH-EASTERN COUNTIES SECTION (at the Central Library, Hempstead Road, Watford), at 7.30 p.m.—Dr. F. Wokes: "Nutrition in relation to Post-War Problems". (To be repeated on Saturday, March 20, at 3 p.m., at the South-East Essex Technical College, Longbridge Road, Dagenham.)

Tuesday, March 2

UNIVERSITY COLLEGE LONDON (in the Anatomy Theatre, Gower Street, London, W.C.1), at 1.15 p.m.—Prof. J. Z. Young, F.R.S.: "The Brain and its Functions".*

CHEMICAL SOCIETY, LEEDS SECTION (joint meeting with the LEEDS UNIVERSITY CHEMICAL SOCIETY, in the Chemistry Lecture Theatre, The University, Leeds), at 5 p.m.—Film Display of Scientific Films; at 6.30 p.m.—Prof. J. A. V. Butler: "The Protein Molecule and its Degradation by Enzymes".

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 5 p.m.—Mr. Roger Duff: "Digging up the Moa Hunters—an Earlier Phase of Maori Culture".

UNIVERSITY COLLEGE LONDON (in the Physiology Theatre, Gower Street, London, W.C.1), at 5 p.m.—Dr. L. E. Bayliss: "Some Aspects of General Physiology". (Further Lectures on March 9, 16 and 23.)*

KING'S COLLEGE (Strand, London, W.C.2), at 5.30 p.m.—Prof. C. A. Coulson: "Quantum Theory in Physics and Chemistry". (Inaugural Lecture in the Chair of Theoretical Physics.)*

CHEMICAL SOCIETY, DUBLIN SECTION (at University College, Dublin), at 7.30 p.m.—Sir Ian Heilbron, F.R.S.: "Recent Developments in the Vitamin A Field" (Pedler Lecture).

Wednesday, March 3

MANCHESTER METALLURGICAL SOCIETY (at the Engineers Club, Albert Square, Manchester), at 6.30 p.m.—Mr. E. Mills: "Metallurgical Problems arising from the Use of Non-Ferrous Metals in the Telecommunication Industry".

INSTITUTE OF WELDING, MANCHESTER AND DISTRICT BRANCH (in the Reynolds Hall, College of Technology, Manchester), at 7 p.m.—Mr. E. McMinn: "Welded Tubular Structures".

Thursday, March 4

UNIVERSITY COLLEGE LONDON (in the Anatomy Theatre, Gower Street, London, W.C.1), at 1.15 p.m.—Prof. S. E. Hollingworth: "Geology—a Preliminary to Planning".*

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Discussion on "Calculating Machines" (to be opened by Prof. M. H. A. Newman, F.R.S.).

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Sir Lawrence Bragg, F.R.S.: "Current Research Work in the Cavendish Laboratory". (Further Lectures on March 11 and 18.)

KING'S COLLEGE (Strand, London, W.C.2), at 5.30 p.m.—Prof. S. W. Wooldridge: "The Role and Relations of Geomorphology". (Inaugural Lecture in the Chair of Geography.)*

INSTITUTE OF PETROLEUM, LONDON BRANCH (at Manson House, 26 Portland Place, London, W.1), at 6 p.m.—Inaugural Meeting; Mr. J. A. Oriel: "Petroleum in the Modern World".

SOCIETY OF INSTRUMENT TECHNOLOGY, NORTH-WEST SECTION (at the College of Technology, Manchester), at 7.15 p.m.—Dr. R. M. Ruhemann: "The Measurement of Low Temperatures".

CHEMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 7.30 p.m.—Prof. E. L. Hirst, F.R.S.: "The Occurrence and Significance of the Pentose Sugars in Nature, and their Relationship to the Hexoses" (Hugo Müller Lecture).

Friday, March 5

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Annual General Meeting; Dr. G. M. Bennett, F.R.S.: "The Proximate Analysis of Mixtures by Methods depending on Differential Solubility and Saturation".

INSTITUTION OF ELECTRICAL ENGINEERS, MEASUREMENTS SECTION (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. A. Butterworth: "Development and Use of Magnetic Apparatus for Bomb and Mine Location"; Mr. B. Roston: "Development of Locators of Small Metallic Bodies Buried in the Ground".

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at the Mining Institute, Newcastle-upon-Tyne), at 6.15 p.m.—Mr. W. Muckle: "Resistance to Buckling of Light Alloy Plates"; Dr. E. G. Richardson: "Measurement of Water Movements Associated with Ships".

SOCIETY OF CHEMICAL INDUSTRY, MANCHESTER SECTION (in the Chemistry Lecture Theatre, The University, Manchester), at 6.30 p.m.—Prof. Arne Tiselius: "Some Recent Advances in Adsorption Analysis".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Sir Edward Salisbury, F.R.S.: "Flowers of Spring".

CHEMICAL SOCIETY (joint meeting with the UNIVERSITY COLLEGE OF SWANSEA STUDENTS' CHEMICAL SOCIETY, at University College, Swansea).—Prof. F. S. Spring: "The Antibacterial Compound, Aspergillic Acid".

Saturday, March 6

INSTITUTE OF ECONOMIC ENGINEERING, MIDLAND REGION (at the Chamber of Commerce, Birmingham), at 2.30 p.m.—Mr. D. R. Burrows: "Rubber and its Manufacture".

SCHOOL NATURE STUDY UNION (at the City Literary Institute, Stukeley Street, Drury Lane, London, W.C.2), at 2.30 p.m.—42nd Annual Conference; at 3 p.m.—Prof. S. W. Wooldridge: "Geology and the Study of Natural Environment".

LONDON COUNTY COUNCIL (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Dr. A. Bake: "Ladakh and the Dances at Hemis Monastery".*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT EXPERIMENTAL OFFICERS (2) in a team which is to carry out research work on insecticides at Porton for the Colonial Insecticides Committee—The Under-Secretary of State, Research Department, Colonial Office, Palace Chambers, Bridge Street, London, S.W.1 (March 8).

ASSISTANT CURATOR at the Royal Botanic Gardens, Kew—The Secretary, Civil Service Commission, 6 Burlington Gardens, London, W.1, quoting No. 2113 (March 12).

ASSISTANT LECTURER IN CHEMISTRY—The Registrar, The University, Sheffield (March 13).

ASSISTANT LECTURER IN PHILOSOPHY—The Registrar, The University, Manchester (March 13).

RESEARCH WORKER (temporary) IN THE DEPARTMENT OF ANIMAL HEALTH—The Registrar, University College of Wales, Aberystwyth (March 14).

ANALYTICAL CHEMIST IN THE DEPARTMENT OF GEOLOGICAL SURVEY, Southern Rhodesia—The Secretary, Office of the High Commissioner for Southern Rhodesia, 429 Strand, London, W.C.2 (March 15).

LECTURERS IN MATHEMATICS (pure or applied)—The Registrar, King's College, Newcastle-upon-Tyne (March 15).

CHEMIST-IN-CHARGE (temporary) at the Royal Ordnance Factory, Birtley, Co. Durham, under the Ministry of Supply—The Ministry of Labour and National Service, Technical and Scientific Register, Room 669, York House, Kingsway, London, W.C.2, quoting F.135/48A (March 16).

CHEMIST-IN-CHARGE (temporary) at the Royal Ordnance Factory, Nottingham, under the Ministry of Supply—The Ministry of Labour and National Service, Technical and Scientific Register, Room 669, York House, Kingsway, London, W.C.2, quoting F.413/48A (March 16).

PRINCIPAL LECTURERS, SENIOR LECTURERS, and LECTURERS, IN MECHANICS, MACHINES, MATERIALS AND STRUCTURES, HEAT ENGINES, ELECTRICAL ENGINEERING, and TELECOMMUNICATIONS, at the Military College of Science, Shrivenham, Swindon—The Secretary, Civil Service Commission, Scientific Branch, 27 Grosvenor Square, London, W.1, quoting No. 2119 (March 22).

METEOROLOGISTS (2) as Professional Assistants in the Royal Observatory in Hong Kong—The Director of Recruitment (Colonial Service), Colonial Office, 15 Victoria Street, London, S.W.1 (March 22).

TOBACCO OFFICERS (General) and TOBACCO OFFICERS (Special) in the Professional Officers' Grade in the Tobacco Branch of the Department of Agriculture, Southern Rhodesia—The Secretary, Office of the High Commissioner for Southern Rhodesia, 429 Strand, London, W.C.2 (March 26).

ASSISTANT DIRECTOR OF NATIVE AGRICULTURE to the Government of Southern Rhodesia—The Secretary, Office of the High Commissioner for Southern Rhodesia, 429 Strand, London, W.C.2 (March 26).

UNIVERSITY DEMONSTRATOR IN PHYSICS, and a UNIVERSITY LECTURER IN PHYSICS—The Secretary, Appointments Committee of the Faculty of Physics and Chemistry, Chemical Laboratory, Pembroke Street, Cambridge (March 31).

ASSISTANT PROFESSOR OF MINING ENGINEERING at Fouad I University, Giza, Egypt—The Director, Egyptian Education Bureau, 4 Chesterfield Gardens, London, W.1 (March 31).

JUNIOR CHEMISTS (female) for service in Tanganyika Territory in connexion with a Fertilizer Research Scheme—The Under-Secretary of State, Research Department, Colonial Office, Palace Chambers, Bridge Street, London, S.W.1 (April 3).

LECTURER IN PSYCHOLOGY (including Experimental Psychology)—The Secretary, The University, Aberdeen (April 15).

ASSISTANT LECTURERS or LECTURERS IN (*a*) PURE MATHEMATICS, (*b*) APPLIED MATHEMATICS, and (*c*) STATISTICS—The Registrar, The University, Leeds 2 (April 17).

PLANT BREEDERS (2), primarily for cereals—The Secretary, School of Agriculture, Cambridge (April 30).

ENTOMOLOGIST IN THE MEDICAL DEPARTMENT (Yellow Fever Research Institute), Nigeria—The Director of Recruitment (Colonial Service), Colonial Office, 15 Victoria Street, London, S.W.1.

RESEARCH ASSISTANT (male) IN THE MECHANICAL WORKING DIVISION—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1, quoting 'Mechanical Working Division'.

RESEARCH ASSISTANT to work on new biological methods of hormone assay—Prof. N. F. Maclagan, Westminster Hospital Medical School, 17 Horseferry Road, London, S.W.1.

TECHNICIAN IN THE DEPARTMENT OF ANATOMY—The Secretary, University College London, Gower Street, London, W.C.1, quoting "Anatomy/1".

BRITISH COLONIAL DEVELOPMENT

THE debate in the House of Commons on January 20 on the occasion of the third reading of the Overseas Resources Development Bill was poorly attended ; the apparent lack of interest was the more remarkable, since, as Mr. Creech Jones quite rightly said in moving the third reading, the Bill had the general support of all political parties and had been acclaimed with some enthusiasm outside the House. The Secretary of State for the Colonies asserted, indeed, that the Bill was as much designed for the purpose of meeting the needs of the world as for meeting the special needs of the Colonial peoples. As Sir Frank Stockdale pointed out in a discourse at the Royal Institution on January 23 (see p. 337), it marks a further big step forward in the British conception of Colonial development, from the social and economic schemes planned under the Colonial Development and Welfare Acts of 1940 and 1945, in exploiting the economic resources for the general development of these territories.

Mr. Creech Jones said he is satisfied that, under the Bill, the needs of Great Britain and Western Europe will not dominate the essential development requirements of the Colonial peoples themselves, and no apprehension need be felt that the provision for an Overseas Food Corporation will divert us from the main purpose of building up Colonial standards. The intervention of the Minister of Food, through the establishment of this Overseas Food Corporation, in matters that should be the responsibility of the Colonial Secretary was the main point at issue in the debate. Mr. Creech Jones believes that the creation of such corporations can give enormous assistance to enterprise ; and in announcing that on the Colonial Development Corporation, the chairman, Lord Trefgarne, would have the support of Sir Frank Stockdale as full-time deputy-chairman, he showed that, as Mr. Oliver Stanley said later, the Government is calling on people of exactly the character and experience which seem desirable. Others who have accepted the invitation to join the Board include Mr. E. C. Tansley, formerly marketing director of the West African Produce Control Board, Sir Miles Thomas and Sir Charles Darwin. Mr. J. Rosa, who was on the Commission of the East African groundnut scheme, links up the Board with the Overseas Food Corporation.

Before making this latter announcement, the Minister of Food had again rejected amendments designed to exclude the Overseas Food Corporation from the Colonial territories, or to enable its projects to be transferred to the Colonial Development Corporation. Mr. Strachey was not altogether convincing as to why two Corporations should be necessary, and he did not dispose of the argument that the Government has allowed to stray into Colonial affairs a by-product of its own failure to deal with the large and vital question of the organisation of government and the division of functions and responsibilities at the highest level, on which the Select Committee on Estimates commented so pointedly in a recent report. For the rest, however, there was only welcome for the general purpose of the Bill, though some wished to see an industrial development scheme linked up with the activities contemplated in the present Bill. While it was obvious that welfare considerations were prominent in the minds of members generally, and that it was the intention of the House that the Development Corporation should use its powers to promote the health and nutrition of the Colonial peoples and to further the prevention as well as the cure of disease, it was equally clear that they had not forgotten the close connexion between our ability to develop Africa and the survival of Britain, to which the Chancellor of the Exchequer had referred.

There are, however, very real dangers in the pace at which political development is proceeding. Their reality is well indicated in a recent book by Mr. O. Awolowo*. Its forthright definition from the African side of the common purpose for which the British and the Nigerians have to work is the product of hard thinking as well as of strong feeling; and even if the latter sometimes tends to discolour the thought and lead to some misinterpretation of the facts, as Miss Perham suggests in her foreword, that does not detract greatly from the inherent value of the book. The book, moreover, has a certain representative importance; as Mr. Awolowo believes that concurrent developments in the Gold Coast are not limited in their significance to Nigeria, so the mental 'climate' of the Nigerian people has an importance far beyond Nigeria. Any constructive contribution from the Colonial peoples has a general as well as a local and particular significance, particularly in meeting the demands which the Colonial situation makes upon our intelligence and the continuous attention which for some reason or other the House of Commons seems unable to give.

The importance of this factor is well brought out by Miss Perham. The main barriers between the British and the small educated minority among the Nigerians and other Colonial peoples are psychological rather than in the sphere of practical politics. This, of course, underlines the importance of that policy of expansion of higher education in the Colonial Empire to which we have already committed ourselves as a result of the reports of the Asquith and Elliot Commissions on Higher Education in the Colonies and in West Africa. But it means also that we should bend our energies and intelligence to the achievement of self-government within the British Commonwealth with something of the sense of urgency which Mr. Awolowo attaches to it, and with a new resolution to make the task of administrative education succeed.

Mr. Awolowo's book deserves attention; but it should be remembered that co-operation along this path involves obligations not only upon the part of the British but also upon the Africans themselves. Moreover, that co-operation is seriously hindered by the distortions of history which propaganda continues to disseminate. Here, as so often elsewhere, propaganda is a deadly enemy of real advance and achievement; it is most effectively countered by accurate knowledge, and the whole trend of Colonial development in recent years has brought the scientific worker into a position where he must not only be increasingly responsible for supplying much of the factual knowledge required, but also himself needs for the execution of his duties more background knowledge of the political and economic situation in which his scientific contribution is being made. It will be noticed, for example, that Mr. Awolowo, who recognizes that the best interests of the coloured peoples lie in co-operating wholeheartedly with those white groups which support their development, considers health and education to be the only important functions of government which the coloured peoples can at present discharge with efficiency. Here Mr. Awolowo's book is often suggestive even where he may be biased and perhaps subconsciously not quite accurate in his presentation. But to the trained mind accustomed to sift and weigh evidence, his frankness and sincerity, his appreciation of the British, for all his impatience, give his book a real value in understanding the mind of the Colonial peoples.

No one who followed the debate in the House of Commons on January 20 could doubt the reality of the desire for effective co-operation between the Colonial and the British peoples, or of the appreciation of the extent to which such co-operation must depend on the calibre of those responsible for handling the educational, labour and medical sides of the work of the Overseas Food and the Colonial Development Corporations. Like the admirable survey of Colonial administration during the war years and the opening phase of reconstruction which the Colonial Office issued last year*, it afforded an impressive tribute to British policy and administration during that time of stress. Unlike that Blue-book, however, the debate testified to the support which the new developments have drawn from all parties of the House of Commons, and indicates once more that differences of opinion as to method or detail have not hindered support for the general policy or impeded the flow of constructive suggestion.

This comprehensive Blue-book is valuable from several points of view It replaces the annual reports on the work of the Colonial Office, publication of which, interrupted by the War, is now to be resumed. In addition, it has the merit of bringing out certain consequences of the impact of the War common to all the Colonies in spite of the differences in their material fortunes. The very prominence which such developments as the East African groundnut scheme and the plan for the development of Uganda give to particular aspects makes it important that such projects should be seen in perspective against the broad background of general policy and those features in the British Colonial Empire which are independent of race and place.

This is the more important because, on one hand, of the increasing approach to Colonial affairs by international collaboration, quite apart from the influence of the Trusteeship Council of the United Nations, and, on the other, because a number of studies of special aspects of the problems of particular areas require consideration against that general background; many have their own contribution to make to the solution of the general problem or of specific problems in other areas. A comprehensive perspective is important in appraising the significance of some of the recent changes and moves in government, such as the appointment of Lord Listowel as Minister of State for the Colonies, and Mr. H. A. Marquand's mission to Africa to discuss general trade developments with the Union of South Africa and Southern Rhodesia, and other developments in regional organisation outlined in this survey. The appointment to West Africa of a resident Minister of Cabinet rank has, for example, been perpetuated in the formation of a West African Council of the Governors of the four colonies, with its permanent secretariat, and the Conference on West Indian Federation in Jamaica last September over which Mr. Creech Jones presided, are no less notable as evidence of Britain's readiness to place her unrivalled political experience at the disposal of the Colonial peoples in their progress to self-government.

* Path to Nigerian Freedom. By Obafemi Awolowo. Pp. 137. (London: Faber and Faber, Ltd., 1947.) 7s. 6d. net.

* The Colonial Empire (1939–1947). (Cmd. 7167.) (London: H.M. Stationery Office, 1947.) 2s. 6d. net.

Such steps indicate how fully the Government appreciates that the changed needs of the time call for an increasing devolution of authority, as well as for the closer integration of government on democratic lines. Moreover, the whole range of government has to be extended so that it may become the instrument of economic and social as well as of political development. Sir Stafford Cripps told the Governors' Conference in November that we are to increase out of all recognition the tempo of African development. Accordingly, just when it is important that new developments of democratic institutions should be firmly based and suited to the capacity of the peoples concerned, it has become imperative that the far-reaching changes involved in the relations of governors and governed should be carried through as expeditiously as possible. Any undue time-lag between new legislative and administrative conceptions in Britain and their application to Colonial policy may, indeed, become a positive danger.

NUCLEAR PHYSICS IN PHOTOGRAPHS

Nuclear Physics in Photographs

Tracks of Charged Particles in Photographic Emulsions. By C. F. Powell and G. P. S. Occhialini. Pp. ix + 124 (50 plates). (Oxford: Clarendon Press; London: Oxford University Press, 1947.) 18s. net.

THE epoch-making discoveries in the field of nuclear physics during the past thirty years have been predominantly due to the development and use of methods of detection of single fast-moving nuclei and electrons. In the experiments of Lord Rutherford upon the scattering of α-particles which established the concept of the nuclear atom, in the discovery of the neutron and of artificial transmutation, and in the more recent investigations upon cosmic rays leading to the discovery of the positron and the meson, the part played by the detectors of single charged particles and quanta has been universal and indispensable. It is, therefore, very surprising to reflect that practically all this work has been done with only four basic techniques: the scintillation screen, the Geiger counter, the ionization chamber plus amplifier and the expansion chamber.

For a long time the possibility of direct recording of the tracks of ionizing particles in photographic emulsions has been recognized, but until the immediate pre-war years comparatively few serious experiments had been made by this technique owing to its limitations and insensitivity. During the past ten years, however, Dr. C. F. Powell and his collaborators at the University of Bristol have taken a leading part in the application of this method to a wide range of nuclear investigations, and, with important improvements in the production of more suitable emulsions by Messrs. Ilford, this technique now ranks in power and efficiency with the counter and expansion chamber. The publication of a book by these authors, illustrating so clearly the present potentialities and limitations of the method in expert hands, is, therefore, noteworthy and welcome.

The volume under notice is not, however, a detailed account either of the techniques of preparation and processing of the emulsions or of the experimental arrangements for exposure and measurement of the plates. It is rather, as implied by the title, an album of fifty beautiful photomicrographs illustrating a great variety of nuclear processes. In the brief space of seventy pages of text, the authors make a praiseworthy effort not only to explain the particular phenomena recorded in the photographs, but also to give an elementary account of atomic and nuclear structure and of the basic phenomena of nuclear physics and cosmic rays. It is only natural that such a limited text will confine the educational value, in a formal sense, to students and school teachers, and even for these the absence of phenomena concerning electrons, which are not recorded by this technique, causes a grave lack of generality and balance. However, such criticism is perhaps unreasonable. The avowed purpose of the authors is to present nuclear phenomena in "the robust form and vivid colouring of physical illustrations" which has greater appeal to many minds than purely mathematical expressions. This volume will, I think, be best appreciated by those who can travel, in imagination, with the meson along the tortuous path in the photograph and wonder at the events transpiring at its brief halting point.

Despite the textual limitations, therefore, the authors are to be congratulated on having produced a volume which every experimental-nuclear physicist will wish to possess, together with the "Atlas typischer Nebelkammerbilder", by Gentner, Maier-Leibnitz and Bothe, which plays a similar part in relation to work which has been done with the expansion chamber. These two volumes have a beauty both of subject-matter and of artistry of reproduction comparable in every way with that of the illustrated books which are so common in the realm of the fine arts. Scientific workers can use them to refute the narrow dogma that "Science deals with facts and Arts with values", which is frequently advanced by their classical friends. We should, indeed, do well to persuade these latter to add these volumes to their own libraries.

P. I. DEE

PHYSICAL PATTERNS OF SPEECH

Visible Speech

By Ralph K. Potter, George A. Kopp and Harriet C. Green. (Bell Telephone Laboratories Series.) Pp. xvi + 441. (New York: D. Van Nostrand Co., Inc.; London: Macmillan and Co., Ltd., 1947.) 25*s*. net.

AS pointed out by Dr. Oliver E. Buckley in the foreword to this book, improvement in the telephone and extension of its service are the principal aims of research in the Bell Telephone Laboratories. It is well known, however, that from these Laboratories have come many other devices which have been of very considerable value to the community quite apart from the use of the telephone. It will be recollected that, shortly before the War, Homer Dudley published the results of fundamental research which had been carried out there on the formation of speech sounds. This may have applications in the future in the field of long-distance telephony. A little later another instrument was devised for the analysis of speech sounds and named the 'sound spectrograph'. This background, which does not appear in the book, makes the development which it describes the more interesting.

The title of the book, "Visible Speech", is the same as that of a book published by the father of Alexander Graham Bell, the inventor of the telephone. The elder Bell's work, however, was only concerned with the use of hand-written symbols which would define the accenting of words more precisely. The sound spectrograph, on the other hand, is essentially a device for making recorded patterns showing the frequency and intensity of the components in short samples of speech. As a first stage in its operation, the speech is recorded on a magnetic tape or by other means. The recorded sample of speech is then scanned electrically many times in succession by means of a circuit which includes a variable-frequency band-pass filter. The result of this analysis may be presented as a photographic record in which time is represented horizontally, frequency vertically and the intensity of the sound by the density of the record. Such records are useful in a study of speech sounds; but in order to enable the deaf to carry on a conversation more direct presentation of the speech in visual form is needed. Various means of doing this are possible: the final result in one case is presented on the screen of a cathode ray tube.

The techniques do, however, make possible methods of depicting speech sounds in such a way that they can be comparatively easily recognized. They have been explored as a means of conveying the information in speech sounds to the totally deaf, and of teaching them to speak by way of training them to reproduce the patterns. It is interesting to note that some of the most useful contributions to the later work have been made by a congenitally deaf engineer. The early part of the book is largely concerned with the description of the patterns which are produced by the basic sounds in speech. The relationship of these fascinating patterns to the use which the speaker makes of his different speech organs, and the basic phonetic principles underlying the patterns, are discussed; information bearing clues which enable a student to recognize and interpret them are pointed out. Although to a beginner the vowel sounds are distinctive, it would seem to him that long practice would be needed to pick out the consonants which convey so much of the information in speech.

The second part of the book, and the bulk of its pages, are occupied by lessons units copiously illustrated with patterns of American speech. This part has been written to be studied by the adult who wishes to learn how to read visible speech, and is adapted to one who either has hearing, or has relatively recently lost hearing, so that sounds and words may be recalled. To be appreciated it must be studied carefully and the various sounds practised and imitated from the patterns.

The experimental work that has been done so far has provided assurance that the patterns of visible speech are distinctive and can be interpreted. It has indicated that visible speech can possibly be used in the speech and general education of the deaf. It is fair to say, however, that a great deal of work so far has been with subjects who have been capable of quickly appreciating the speech patterns; but the practical value of visible speech as a means of making contact with the normal deaf person of no more than average education and intelligence has yet to be evaluated. As the authors say, the primary purpose of the book is that of turning over to all those who would carry on the work the major results and development to date.

This book can be unreservedly recommended to all those who have a specialist's interest in speech sounds, and in particular to those who are intimately concerned with the interests of the deaf. 'Visible speech' may also have other more varied applications, both as a research tool or for more widespread use; but these will emerge later. W. G. RADLEY

MODERN RADIO TECHNIQUE

(1) A Survey of the Principles and Practice of Wave Guides

By Dr. L. G. H. Huxley. (Modern Radio Technique Series.) Pp. xi+328. (Cambridge: At the University Press, 1947.) 21*s*. net.

(2) Radio Aids to Navigation

By Dr. R. A. Smith. (Modern Radio Technique Series.) Pp. xii+114+7 plates. (Cambridge: At the University Press, 1947.) 9*s*. net.

THE introduction of radar and the widespread development of radio wave technique during the past ten years have resulted in a considerable addition to our knowledge and experience, the records of which were confined during the war years to confidential and secret reports. Much of this information has recently been published in the form of scientific and technical papers in the proceedings of societies and institutions. There is clearly a need in addition, however, for a more compact form of publication in which the information on various aspects of the subject is collected together in separate volumes or books. It is therefore gratifying to note the proposal by the Cambridge University Press to publish a new series of monographs under the editorship of Mr. J. A. Ratcliffe and dealing with the advances in radio technique made during the War. All the monographs are being prepared by men who were personally responsible for important advances in the subjects they write about; two volumes have already been published, and some six more are in active preparation.

(1) Although the subject of the propagation of electric waves in metal tubes—or wave guides as they are now called—has been studied theoretically

for some fifty years, it was not until radar technique began to be developed on centimetre wave-lengths that the subject suddenly became of outstanding practical importance. Dr. Huxley was, during the War, head of the Radar School of the Telecommunications Research Establishment, and thus had a unique opportunity of becoming fully acquainted with the development of the subject, and the manner in which it should be treated for teaching purposes. The first six chapters of his book are based on courses of instruction on microwave techniques given at the above School, while the seventh and last chapter contains a more systematic mathematical treatment of various matters dealt with earlier.

This is a very satisfactory arrangement, for the reader who is not mathematically inclined will find that the early chapters, which comprise about three-quarters of the book, provide an extremely clear exposition of the phenomena associated with wave guides, and of the many practical applications of wave-guide systems. The reader is introduced to the conception of the transmission of waves having electric or magnetic field components in the direction of transmission by considering the superposition of the fields of a series of transverse waves travelling at an angle to the axis of the guide and being subjected to repeated reflexions from its walls. The phenomena of multiple-mode transmission and the frequency cut-off characteristics of wave guides are also clearly described. Among the practical topics dealt with in Chapters 4 and 5 are standing-wave detectors, crystal mixers, wave-guide couplers and matching transformers, means of producing circularly polarized waves, and the behaviour and use of slots cut in the walls of the guide. These two chapters occupy nearly half the book, and will be found invaluable by those who have to use wave guides as an essential part of any equipment for centimetre wave-lengths.

Chapter 6 deals with cavity resonators and their various applications, whether as tuned elements in oscillators in place of the conventional lumped circuits, as wavemeters or as echo boxes which are resonators of very low decrement, which when shock-excited by a pulse continue to 'ring' or emit a radio signal for an appreciable time after the cessation of the exciting pulse. This chapter also contains an indication of the manner in which resonant cavities may be used in the measurement of dielectric properties of materials of interest to the radio engineer and physicist.

The book is well produced and liberally illustrated, and it is to be recommended to all classes of reader interested in wave guides; and those concerned with practical applications will find the physical treatment most illuminating.

(2) The author of the second book, Dr. R. A. Smith, also has the advantage of being a member of the staff of the Telecommunications Research Establishment, where remarkable developments in radio technique took place during the war years, following the successful application of pulse technique to the detection and location of aircraft, ships and other objects. The field of radio navigational aids is nowadays very wide, and the author has, perhaps wisely, made no more than a brief mention of the use of medium- and high-frequency direction finding, and the associated developments in radio beacons and radio ranges for course-indicating purposes. Furthermore, the book is, on the whole, concerned with the navigation of aircraft, although some reference is made to the problems of navigation at sea in the two chapters on "Long-Range Navigational Aids" which deal with pulse and continuous wave systems respectively.

Within these limitations, Dr. Smith has provided an interesting account of the radio navigational aids developed primarily in Great Britain. The style throughout is descriptive, and in parts almost of a historical narrative nature; and to the reader with some general knowledge of the subject, the monograph forms a most useful and concise survey of this particular field of development. The author has quite rightly omitted all circuit diagrams and technical details; but sufficient values are given of the performance of the various systems to enable an appreciation to be made of the relative merits and fields of application of these navigational aids, some of which are now being adapted to the needs of civil aviation and merchant shipping.

It is very satisfactory to see material which has hitherto been scattered over a number of published papers and confidential reports collected together and presented in this way for the general scientific reader. For the benefit of those who wish to delve deeper into the subject, some references are given to recent detailed publications, many of which are the result of the Radiolocation and Radiocommunication Conventions held by the Institution of Electrical Engineers in 1946 and 1947 respectively.

R. L. SMITH-ROSE

MODERN INORGANIC CHEMISTRY

Modern Advances in Inorganic Chemistry

By E. B. Maxted. Pp. vii + 296. (Oxford: Clarendon Press; London: Oxford University Press, 1947.) 20s. net.

THE last two or three decades have seen very substantial advances in inorganic chemistry, as regards both technique and the fundamental concepts on which the subject is based. Any volume which succeeds in making a critical survey of the field so opened up is therefore most welcome.

Most needed at the present time, perhaps, is a concise account of the physical background to inorganic chemistry, which would enable the student to obtain a sufficient grasp of atomic and nuclear physics to follow current developments in the theory of valency and in artificial radioactivity. The first chapter of Dr. Maxted's book sets out to provide such an introduction, but, unfortunately, falls short in several particulars of what might well have been achieved. It is surely essential that the account should be authoritative, and that points settled beyond any reasonable doubt should be presented in a clear-cut manner. In this respect the section on nuclear structure is not at all satisfactory; it contains a number of cautious understatements of well-established facts, coupled with a few rather positive assertions on matters which are by no means finally settled. The remainder of this chapter is devoted to an account of modern ideas of valency, as developed by Pauling and others.

The following chapters give more detailed accounts of recent work on a few specialized topics. Some of these subjects are dealt with in a completely satisfactory manner—the chapter on the "Recent Chemistry of the Halogens", for example, appears to be unexceptionable—and it is therefore all the more disappointing to have to record that this state of affairs does not appear to extend to some questions for which a more critical outlook is required.

Perhaps the most serious example occurs in the chapter "Masurium and Rhenium". Here, the author does not appear to be at all perturbed by the absence of any confirmation of the claim of Noddack and Tacke to the discovery of element 43. The reviewer feels that the very least that should be done in this case is to make it abundantly clear that the existence of stable isotopes of this element is still an open question. The uncritical reproduction of published work is evident also in the discussion of the hydrogen isotope of mass 3. The author records the abundance of tritium in ordinary water as about 7 parts in 10^{10}, as reported by Selwood, Taylor, Lozier and Bleakney; he does not appear to wonder how so short-lived an atomic species (its half-life is about thirty years) could continue to exist even in this small concentration. In point of fact, subsequent experiments led Bleakney and his collaborators to retract their claim in favour of a much lower figure for the upper limit of abundance, and yet more recent work has set the upper limit at 1 part in 10^{17}.

The remainder of the purely inorganic part of the book calls for little comment: Chapter 4 on hafnium, and the remainder of Chapter 5, on rhenium, are quite satisfactory; the chapter on the halogens has already been commended. Hydrogen and deuterium are given a fairly adequate treatment in Chapter 2, although on one or two occasions a distinct displacement of emphasis is apparent. Chapter 6 contains a very useful account of "Reactions in Discharge Tubes", a subject which, hitherto, has tended rather to be neglected.

The book concludes with two chapters inspired by the current interest in nuclear reactions: "The Preparation and Uses of Artificial Radioactive Elements" and "Uranium and the Transuranic Elements". For a superficial study of these two related topics these chapters give an adequate account, although it cannot be claimed that the treatment is outstanding. From the book as a whole one is tempted to draw the conclusion that, human fallibility being what it is, reviews covering so wide a range of topics should be a co-operative effort on the part of two or more authors. G. R. MARTIN

EXPERIMENTAL STUDY OF HUMAN HEALTH

Biologists in Search of Material

an Interim Report on the Work of the Pioneer Health Centre, Peckham. Edited by Dr. G. Scott Williamson and Dr. I. H. Pearse. Second edition. Pp. 107 + 2 plates. (London: Faber and Faber, Ltd., 1947.) 5s. net.

THE aims of the Peckham Health Centre are nowadays so well known that they need no explanation here. The plan was to offer to families living within a specified area containing about 5,000 families a health service in the form of a family club, supported by a weekly subscription which is now 2s. per family. This doubling of the original subscription was suggested by old members of the Centre themselves. The details given in this book of the health examinations made show that the families participating obtain for this small subscription a very valuable service. But the scheme would be fundamentally misunderstood if it were thought that it seeks to replace or compete with other health services. It is essentially a biological experiment of a very interesting kind. With the full co-operation of each family it studies this social unit together with its environment, and it is claimed for it that it has also great social and educational value and can be used for the training of medical and social workers.

A short review can do no more than indicate the kind of results so far obtained and direct attention to the originality of the minds which direct the whole experiment. Stating, for example, that the efficiency of medical services depends primarily upon diagnosis, the authors of this book remind us that the first diagnosis is made by the patient. The medical man can do nothing until the patient, because he suffers from pain, discomfort, disability or limitation of action, seeks advice; and observations made at the Centre indicate that the patient seeks treatment, not because of his subjective state of disease, but because he is aware of his social incapacity. The word 'disease' is here used as meaning only the subjective state of the sufferer, the objective facts discovered by the medical man, such as adenoids, rickets, pneumonia, and so on, being called 'disorders'.

The authors' analysis of the condition which they call 'well-being' also presents some interesting observations. Well-being, they claim, can mask both grave and minor disorders. An instance of the former is the youth aged twenty-one, who said he had never felt better in his life and who was able, because he was ambitious to become a boxer and a gymnastic champion, cheerfully to sustain valvular disease of the heart, nephritis, high blood pressure and albuminuria. He compensated, as the authors put it, for his body's shortcomings, but only at considerable cost to his body. The dangers of this kind of compensation, which produces, often at a great price, a balanced action of the whole organism, are well described. This state of well-being, which deceives both the patient and the casual observer, is differentiated from the state of health which exists when the organism is not turned in on itself to effect a compensation, but is exerting an adaptive function to the whole situation and operates on the environment rather than upon itself.

Interesting also is the view that the general practitioner and the outpatients' departments and dispensaries of the hospitals treat maladies in order to relieve the social inconveniences of the patients, such as pain, discomfort, and so on; whereas the specialist tends to study the malady as if it were a detached objective thing. The practitioner thus becomes a highly skilled craftsman in the relief of social disabilities associated with disease, and this is what the patients demand of him. "But it is very clear," say the authors, "that what the public demands and gets from the practitioner is not what the State, the friendly societies and the industrialists expect of the doctor." Nor is this all that the medical man, when he emerges from his training, hopes to give.

Certainly the further progress of this experiment will be watched with the greatest interest. The subsidy required per head at the present expensive experimental stage is £4 15s. per year, a figure which may be compared with the calculation made in this book that £6 per head of the population is wasted every year through illness. The claim is made that, given time, the Centre can be made self-supporting. Let us hope that the solution of this problem of time and money, which is, the book says, the major one still remaining, will quickly be found. G. LAPAGE

FACTORS OF AGRICULTURAL PRODUCTION IN THE BRITISH COLONIAL EMPIRE*

By SIR FRANK STOCKDALE, G.C.M.G., C.B.E.
Adviser on Development Planning, Colonial Office

CONSIDERABLE interest is now being taken by Great Britain in colonial development. This interest has been further stimulated by the Government's decision during the past year to undertake the East African groundnut scheme and to establish a Colonial Development Corporation and an Overseas Food Corporation. The latter, when constituted, will take over the operations of the East African ground-nut scheme and start other food production projects overseas, while the Colonial Development Corporation will deal with developmental projects of a widely varying character throughout the colonial territories—the importance of which has been emphasized in recent months by the difficulties which are being experienced by Britain in the balance of dollar payments.

It is, however, well to realize that this decision by the Government to establish a Colonial Development Corporation is but another advance in Britain's colonial policy, which is designed to improve the standard of living of the colonial peoples, to extend their social services and to advance political self-government. The British people are convinced that the standards of life of the colonial peoples must be raised and that better economic standards in colonial territories will provide expanding markets and a general improvement of world trade.

Improved standards of life cannot be obtained or better social services maintained without expanded production. Indeed, the emphasis in the activities of Colonial Governments in the future is certain to be in the developmental field, and to be directed towards the utilization of the natural resources of the territories to the fullest extent possible, coupled with a general advancement of their peoples.

Looking at the colonial territories as a whole, the one outstanding feature which calls for comment is the very considerable increase of population during the past twenty to thirty years. It is rapidly becoming apparent that the present systems of production may very shortly be unable to provide sufficient food for satisfactory nutritional standards for these increasing populations and that marked changes in the methods of production must be made. In certain places, particularly in Eastern and Central Africa, soil erosion has assumed alarming proportions, and considerable areas, through pressure on the land and by poor systems of agricultural husbandry and stock keeping, have been rendered incapable of further production for many years.

Food will, undoubtedly, figure prominently in the requirements of the future and must be given the highest place in colonial policy. At the same time, if standards of living are to be raised, commercial crops must be grown and a more diversified production established.

I propose here to limit myself to a consideration of some of the factors which influence agricultural production under colonial conditions. They may be dealt with under the following headings: climate, soils, water, systems of agriculture, use of livestock, crop varieties, pests and diseases of man and his stock and crops, marketing arrangements and social organisation.

Climate

The climates of the British Colonial Empire range from the super-humid of the tropical rain belt with its heavy forest, through the humid with its lesser forest or parkland vegetation to the sub-humid with grass-covered savannas and thence to semi-arid steppe or desert with sparse vegetation. Climate, after all, plays the part of master influence on agricultural activities and production, and it determines not only the major soil zones, but also the systems of agriculture which prevail.

In the eastern group of Colonies, the climate of Malaya, Sarawak and North Borneo may be classified as super-humid and that of Ceylon either super-humid, humid or sub-humid according to aspect and altitude. In the West Indies, and the continental territories of British Guiana and British Honduras, the range is similar to that of Ceylon, but there are occasionally years of serious drought.

A study of Africa reveals wide climatic belts which range from super-humid to the semi-arid. Types of vegetation and the agricultural crops correspond to a greater or lesser degree with the different climatic belts. In West Africa, dense equatorial forest covers the coastal regions of the Gold Coast and Nigeria, and extends throughout French Equatorial Africa into the Congo basin. North of this equatorial rain forest occur zones which pass from humid and sub-humid to arid, with corresponding tall grass savanna, dry savanna or desert. In East Africa, humid regions occur as coastal or lake belts, sub-humidity prevailing elsewhere except where influenced by altitude. In Uganda, the area with a humid climate exceeds that under sub-humidity which is characteristic of the other East African territories. At the higher altitudes in East Africa, as well as in the Central African territories, there are zones of mountain forest and grasslands with variable rainfall.

Production in the tropical rain belt with an annual rainfall in excess of 80 in. includes timbers and forest products, oil palms, coconuts, rubber, cacao, bananas, sugar, rice and certain root crops, whereas the production of the drier forest, parkland or grass savanna areas with rainfalls ranging from 30 in. to 60 in. includes coffee, cotton, yams, maize, millets, groundnuts and livestock, and in the areas of low rainfall millets are grown and livestock are found to predominate. In the higher altitudes with rainfalls of 60 in. or more, tea and wattle flourish, and where the rainfall is lower, coffee and some of the crops of temperate zones thrive.

Soils

These cover a wide range and naturally vary in composition according to the nature and age of the rocks from which they have derived. Laterites are common. They contain an appreciable quantity of iron concretions—sometimes resembling lumps of iron ore and sometimes small pebbles. They are caused by the leaching of iron salts from the upper soil layers and their subsequent re-oxidation around particles of quartz. In many areas, particularly where the climate is humid or sub-humid, definite hard pans are formed and these have to be watched for with care. Tropical soils generally are acid in reaction, especially in the wetter areas and where not derived from limestone. Some crops require soils of acid reaction for maximum production and will not thrive when the lime content in the soil is high, while others only prosper where the soils are neutral or only slightly acid in reaction. Throughout the soils of the tropics a deficiency of nitrogen is widespread. Phosphatic deficiency also occurs over wide areas.

---

* From a Friday Evening Discourse at the Royal Institution delivered on January 23.

Climatic factors have their influence upon soil formation; but in general the soils correspond closely with the geological formations and are the product of the rapid weathering of the rocks under the influence of rainfall and high temperatures. There are marked differences between the formation of soils under tropical conditions and those of the temperate regions, although the fundamental scientific principles are the same. Such factors as depth of soil, moisture content, drainage, soil structure and tilth, and the nature of the rocks from which they have derived, all have their influence. The interdependence of these several factors must be recognized.

In the wetter areas of the tropics, weathering is much more rapid than in temperate zones, and the biological activities in the soils are speeded up. Under super-humid conditions a dense growth of rain forest exists; but this luxurious cover must not be taken as an index of soil fertility, because as soon as the forest cover has been removed and the land brought into cultivation, there is a rapid fall in fertility. Nitrogen is leached rapidly by the heavy rains, and the forest floor cover of decaying vegetation is rapidly oxidized and lost. It is, indeed, now recognized that in the very wet areas, where there is no well-marked dry season, it is essential for land to be kept under cover of growing vegetation if soil fertility is to be maintained. Tree crops are the best suited for cultivation under these conditions.

Humus is the regulator of good conditions of tilth and of water distribution under the conditions prevailing in the wet tropics, and with perennial crops under a heavy and well-distributed rainfall, green manuring is the most suitable means of maintaining humus. The chief requisite for the successful use of green manures is the availability in the soils of sufficient moisture to ensure decomposition. A green manure crop must, however, be handled with skill so that the carbon and nitrogen cycles are dovetailed with the growth of the main crop.

It may here also be mentioned that one of the striking features of native agricultural systems in the wet tropics is the system of mixed cropping. There is sound justification for this practice.

In the zones of sub-humid climates the sequence of events is somewhat different from those occurring in the super-humid zones. Here there are marked dry seasons when chemical and biological activities are slowed down through inadequate supplies of soil moisture. Green manuring can be used under these conditions only with care, and in areas where the rainfall is poorly distributed their use may indeed be detrimental because of the drain which these green manures make, during their periods of growth, upon the soil moisture. In areas where there are marked contrasts between wet and dry seasons and where high temperatures prevail in the dry periods, it is difficult to maintain under a system of cropping the content of organic matter in the soils; but these soils do not appear to lose fertility so rapidly as the soils in the wetter areas because the losses from leaching are so very much less. In dry areas, much value has been derived from mulching, and in certain places agricultural production has been dependent upon the adoption of this practice.

In soils in the sub-humid zones, the available nitrogen is greater at the end of a long dry and hot period than at the beginning of the drought. Systems of bare fallow between crops are therefore used. This nitrogen is mainly in ammoniacal form; but with remoistening by rain a rapid biological conversion to nitrate takes place and rapid plant-growth results therefrom. One has only to see the rapid flush of grass after the first rains to realize the importance of this store of nitrogen, and where agriculture is practised the aim must be to make the fullest use of it. Weed-growth flourishes in such conditions and causes losses in crops unless promptly and adequately dealt with. It is this weed-growth which peasant cultivators often find it difficult to control.

Soils in the sub-humid zones are also prone to lose crumb structure and to suffer severely from erosion. Examples are to be found in East Africa.

The use of grass leys has been shown in Uganda and elsewhere to improve the crumb structure of the soil, and this system is now extending there and being tried elsewhere. Grass also is a natural good protection against erosion. In short-grass country, overgrazing of stock can, however, easily bring disaster. It has also been found in many parts of the tropics that farm practices may accelerate the destruction of tilth and that cultivation in excess of what is required to control weeds may depress crop yields. Hence the general tendency to reduce cultivations to those which are necessary for the destruction or suppression of weed-growth. It is under sub-humid conditions that the majority of the lands of colonial territories in Africa are found, and while mixed farming is likely to be the best system for peasant production, other systems involving the use of grass leys and fertilizers will have to be worked out for large-scale production.

Water

While some colonial territories have given special attention to the question of water development, there are many others in which much remains to be done. In general, there is a great scarcity of rural water supplies. Populations in certain areas are crowded together because of the limited development of water over a wider area, and in East Africa there is a serious maldistribution of livestock as a consequence of the inadequacy of the supplies of water for such stock.

Irrigation is a recognized part of the agricultural system in the eastern territories, where rice-growing is an old-established occupation; in Malaya, drainage control must be linked with irrigation. This is also the case in British Guiana on the flat coastal lands and in the coastal and internal swamp areas of Sierra Leone. Irrigation is practised in certain of the drier parts of Mauritius and also in Cyprus, where considerable success has recently been achieved with small village irrigation schemes. In areas where rainfall is normally erratic or deficient or where population increases are causing pressure on the land, the further development of irrigation is essential if increased production is to be achieved.

Systems of Agriculture

These range from highly organised systems under estate management, where considerable use of the services of science has been made, to the most primitive of systems of 'shifting cultivation' for the production of subsistence foods. In the West Indies, science can justify a claim to have been responsible for increased yields of sugar of the order of 25–30 per cent, and in the rubber industry of the Far East, production yields of double or treble those previously obtained from unimproved seedling growths have been achieved since the vegetative propagation of improved strains of rubber has been adopted.

At the same time, it may be safely assumed that productivity could easily be increased by a further 25 per cent in large-scale operations and up to 50 per cent in the smaller holdings from greater efficiency in the methods of husbandry.

At the bottom of the scale is the system of 'shifting cultivation' which is the basic system of subsistence agriculture. This system is still the standard practice of a very large number of the peasant cultivators of Africa and also of other tropical territories in areas where rice cultivation has not been established. These peasant cultivators, in sparsely populated areas, have plenty of land at their disposal, and a system of rotation of land has preference over rotation of crops. This is understandable when land is plentiful and where the people have only the hoe and the axe, in addition to fire, as their aids to the production of their food requirements. They may choose their lands with care, and they may be skilled in the choice of plant indicators of good soils; but their operations are restricted by the tools at their disposal, by the fall in soil fertility which follows the first year of cultivation and, most of all, by their inability to deal with the luxuriant weed-growth, which becomes really troublesome in the second season. It is this weed-growth which is generally the controlling factor in shifting cultivation in the wet tropics.

In some parts of Africa there have been natural evolutions from the primitive system of 'shifting cultivation' to a more settled form of continuing production, especially where cash crops have been established; but in some places it has been necessary to arrange for new settlements because of the low fertility to which the land has been reduced. In such cases, it is not unknown for reluctance to be shown to the abandonment of land occupied by the tribal group in favour of a movement to new sites, because of the beliefs of the people; and this has been even more marked when the occupation of the new land has been conditioned by arrangements for its proper use.

Advances in tropical agricultural systems have, however, in general been most rapid under European management, or where there has been a mingling of large-scale and peasant production. The progress made in the past twenty years has been considerable; but the needs of the next decade will necessitate a revolution in methods of production, especially if the standards of life of the colonial peoples are to be markedly advanced. The hoe system of agriculture will have to give place to other methods; and the introduction of mechanized aids and of fertilizers is inevitable.

Estate cultivations have made increasing use of fertilizers; but the experimental work with fertilizers has been mainly confined to the requirements of the cash or export crops. Little has been done where food crops are concerned except in regard to rice, largely because of the low unit monetary values of these crops. Some useful work has, however, been done in Northern Nigeria and in isolated instances elsewhere; but a wide scheme of fertilizer trials, planned in accordance with the most modern techniques for field experiments, has recently been started in East Africa.

Use of Livestock

Agricultural progress in Western countries has been linked with the use that has been made of livestock, and this has led to the development of important animal industries. In the colonial territories livestock industries are but little developed. It is true that considerable use is made of buffaloes and cattle for draught purposes, as well as in connexion with rice cultivation in the Eastern colonial territories and also for the production of milk and milk products. An important livestock industry also is developing in the highlands of Kenya, where European strains, especially when crossed with selected animals from the native stock, thrive satisfactorily, and where a number of co-operative creameries have been established. Similarly, European strains form the basis of the livestock in the West Indian colonies, and a thriving dairy industry has been developed in Jamaica since the establishment some seven years ago of a milk condensary.

This use of European strains of livestock in tropical areas cannot, however, be general, and reliance has to be placed on the improvement of the native breeds. The heat-regulating mechanism of European cattle is adapted to life in temperate climates, and the high ranges of atmospheric temperatures and humidity, especially where there is a low rate of air movement, cause adverse physiological reactions under tropical conditions. The stock have higher body temperatures, higher respiration-rates and a change in the pulse-rate. European breeds are not suited to those areas in colonial territories where high average temperatures and high humidity prevail, and under these conditions they can only be kept in full productivity when they are maintained under artificial conditions of controlled temperatures, as they were before the War in some special dairies in Singapore. It is only at the higher altitudes where temperate conditions prevail, or in the island territories where air movements are considerable, that European stock can be satisfactorily maintained if the higher plane of nutrition required is available. Even in these conditions it is necessary to provide a sufficiency of shade and to see that the stock are not subjected to the full blaze of the tropical sun between the hours of 10 a.m. and 4 p.m. The crossing of European stock with Indian or the indigenous breeds of Africa has been fairly widely practised. This system can, however, only be used in restricted areas and, in general, selection from the indigenous stock will be the soundest policy.

So far, the livestock of the colonial territories of Africa have been little used in agriculture. The herds are grazed on the natural pastures and move over fairly wide ranges from area to area according to the seasons and the nature of the herbage. Their owners are reluctant to sell them, and agriculturists frequently have difficulty in acquiring stock for their farm needs.

Where there is overstocking, soil erosion and land deterioration can be traced directly to the damaging effects of overgrazing and excessive trampling of the land; but experimental trials have shown that where controlled grazing is practised and where stock numbers are limited to the carrying capacity of the land, considerable improvements can be effected.

In some colonial territories there has been an extension of the use of livestock for the manuring of agricultural land, for the production of dairy products, for the conversion of farm wastes and for purposes of draught. In African territories, however, numbers are placed before quality because of the fear of losses from disease and because the social status of their owners in the community is judged by the number of stock owned. The problem of livestock in Africa is full of difficulties; but it must be tackled resolutely and with imagination if the present damage to land is to be checked, and if an animal industry of full value to the inhabitants of the territories concerned and to the world in general is to be established.

Livestock management by colonial peoples is still very backward even where mixed husbandry or dairying has been established; but it is general to find that peasant farmers with livestock are better off and live at higher standards than do those who possess no livestock.

Crop Varieties

Some reference has already been made to the increased yields which have been secured from the use of improved seed or planting material. In no sphere of the application of science to tropical agriculture has more progress been made.

Sugar cultivations now depend almost entirely upon the growth of improved strains of seedling varieties. Cotton production also requires the continuing production of new types suited to the particular conditions under which they are grown. Rubber growing has been transformed by the selection of high-yielding strains which, when proved, have been propagated vegetatively or planted in special isolated gardens for the production of self-fertilized seed. Similar progress has been made with coffee, cacao and, to a lesser degree, with tea, while the successful cultivation of tung depends entirely upon selection work. Many other examples could be quoted.

In certain areas, breeding work has been done with tropical food crops; but the progress in this field has not been so pronounced as could have been hoped for. The genetics of the genus *Musa*, to which the banana belongs, has received considerable attention at the Imperial College of Tropical Agriculture in Trinidad and also in Jamaica, where large numbers of seedlings have been produced. None of these, as yet, fully meets the commercial requirements of the trade, and a further search for new breeding material is shortly to be made. In Barbados, all sweet potatoes now grown are of seedling origin, and the yields are markedly in excess of those obtained from the earlier standard varieties. Similarly, strains of cassava which are improvements on the earlier types have also been evolved. Marked improvements have been made with rice in Ceylon, in Malaya and in British Guiana. The millets have not, so far, received the attention that should have been given to them, and it is hoped that early steps will be taken to establish special stations in Africa for meeting this need.

Pests and Diseases

In the past, the human diseases of the tropics and the pests and diseases of crops and stock controlled output. Malaria is of frequent occurrence, and its debilitating effects are still considerable. The lessons of certain operations in the Second World War have proved that a large measure of control over malaria is possible, and the value of *D.D.T.* in the control of mosquitoes in houses and villages has already been successfully demonstrated in British Guiana, Uganda, Mauritius and elsewhere, while a large-scale experiment in the Karpas peninsula of Cyprus has given such satisfactory results as to warrant wider trials in that Colony and to the planning of an all-island campaign against malarial-carrying mosquitoes in Mauritius.

The tsetse still holds under its control vast areas of Africa, and trypanosomiasis in man and in stock is still a controlling factor in certain areas. In Tanganyika, it is estimated that two-thirds of the total land area is infested by different species of tsetse flies; vast stretches of that territory are, in consequence, devoid of population. Much research work has been done on tsetse control and some advances have been made.

Among stock diseases, rinderpest, East Coast fever, pleuro-pneumonia and intestinal parasites have to be contended with. Progress has certainly been made by the veterinarians; but rinderpest is still a factor which cannot be regarded with equanimity in the African territories.

Locusts still cause damage to crops from time to time in Africa; but marked advances have been made in our knowledge of the bionomics of the three species of locusts with which colonial territories in that continent have still to contend. The application of control measures based upon this knowledge is steadily continuing, but final success cannot yet be claimed.

Crop pests account for losses, and in certain areas they are a controlling factor. Those of cotton have received special attention, and the work of the entomologists of the Empire Cotton Growing Corporation has been outstanding. A considerable knowledge has been accumulated and this enables an assessment to be made with a fair measure of accuracy of the areas in which cotton cultivation can be extended and those in which such extension would at present be unwise. Control of certain pests of cotton and of several diseases has been achieved by the breeding of resistant strains, although it is still estimated that if the lygus pest in Uganda were controlled, output would be increased by 50 per cent. Similarly, there are still considerable losses during storage, especially in food crops or grains, and these are now under special investigation in West Africa.

Among plant diseases mention should be made of the witches' broom of cacao which has had devastating effects in Trinidad and South America, the swollen shoot virus disease of cacao in West Africa, the die-back of cloves in Zanzibar, the mosaic disease of cassava, the Panama disease of bananas in the West Indies and the bunchy top disease of bananas and manila hemp in the East. The virus disease of cacao has already caused the loss of nearly one-third of cacao production in the Gold Coast. A special West African Cacao Research Institute has been established [see *Nature*, January 24, p. 117] and very considerable progress has been made. It is, however, unlikely that the disease will be finally defeated until new types immune or resistant to the virus have been found. Further expeditions in search of new strains of cacao from South America are contemplated and, in order to assist banana producers, a scientific expedition to collect wild species of *Musa* from south-east Asia is in process of being arranged.

Marketing Arrangements

Marketing arrangements and the prices of commodities have their place of importance in the efforts of all producers and agriculturists, as well as others. Price fluctuations often affect total production, and frequently the productivity of individual producers or groups of producers. When prices are low, agriculturists tend to cut out maintenance works, and efficiency suffers. The fluctuations and the general trend of low prices for primary products between the two World Wars were not without their effect upon efficiency of production in the colonial territories.

The Second World War saw the introduction of bulk buying and selling of certain colonial commodities, and this system has introduced a system of agreements under which prices have been fixed by negotiation.

The value of such a system was appreciated by colonial producers, as it enabled them to plan their production ahead with some measure of confidence. Peasant producers have also benefited from, and have generally recognized the value of, the systems of price fixing which were adopted. There have, however, been fears that these arrangements could not be continued, and at the present moment further consideration is being given to the matter. Commodity marketing organisations are being continued, and steps are being taken to build up price equalization funds so that when prices fall the producers will not suffer unduly. Contracts for purchase of some commodities now include provision for (*a*) equipment replacement, (*b*) the building up of price equalization funds, and (*c*) expenditure on welfare amenities for the labourers employed.

The above arrangements relate to export commodities, and they should have a stabilizing and encouraging effect on production; but there are some who still contend that the contract periods are of too short a duration. Production for home consumption in the Colonies, especially of foodstuffs, would be stimulated if price-regulating methods similar to those contemplated under the recent United Kingdom Agriculture Act could be brought into effect.

Social Organisation

In the West Indies and some of the older Colonies, lands have from the first been held on forms of tenure and title similar to those prevailing in the United Kingdom, and social organisation has followed, with adaptations, the English pattern. In others, the forms of tenure have originated in indigenous customs which were an integral part of the social structure. In the African territories and also in some others, this structure, which is based upon the village, is built upon communities. Rights to particular plots of land are often recognized; but these rights are limited to the period of occupation, restricted as to succession and qualified by membership of a kinship, clan or other group. These plots are usually small in size, and the community interest generally prevails so far as land is concerned. This is usually not the case in respect of the produce from the land.

Customary rights have undergone, and still are undergoing, a rapid process of change as the result of economic influences. The expansion of education, as well as the development of urban areas, and of mining, have had their effects. Introduction of new types of crops and of new methods of agriculture also have brought about important changes. The introduction of permanent tree crops such as cacao and coffee, for example, has resulted in a firm growth and expansion of the conception of ownership as against the previously held conception of a collective right in land derived from indigenous custom, and changes have been accelerated by the necessity for adjustment to the needs of modern economy of production and marketing. In some territories defined native reserves have been established, and in others there are to be found land tenures based upon the indigenous customs alongside those which have been introduced from elsewhere for alienated lands.

It is impossible to deal here, however, with the varying systems of land tenure which are found in colonial territories, to the tribal restraints which are sometimes imposed upon enterprise and initiative, or to discuss the strains and stresses which are resulting from the spread of education.

Productivity of land, however, depends as much upon sound systems of land tenure as upon improved agricultural practices, and any policy of development must increase the range of land matters and social issues to which colonial administrations will have to give urgent attention. It would seem that a solution of the social issues involved must lie in finding a balance between the advantages and disadvantages of the traditions of the past, the customs of the present and the needs of the future. Bold experiments may have to be made.

Conclusion

I have attempted, briefly, to review those factors which affect production in colonial agriculture. They are many and varied, and several of them are interdependent. In the early stages of colonial endeavour empirical measures sufficed, but these have gradually given place to methods which are being evolved on an ever-widening basis of knowledge. The man of science and the administrator are equally concerned, and a closely knit partnership between them must be established for the combined operations which are required.

Science has an important part to play. All research work must be planned in such a way that it is relevant to the objectives in view, and the utilization of this knowledge must be regarded as a duty of the administrative machine.

In agriculture, the scientific research worker should have full and frequent contact with production at all stages and with the persons engaged in that production. Without this contact, research is liable to become sterile and ineffective. Research organisations for specific industries, when they can be afforded, have their value, as they do ensure that the results of their work are translated quickly into practice. When, however, research work is planned on a wider basis, steps must be taken to ensure that it is not divorced from those charged with helping the advancement of the cultivators of the land. The chain must be complete to be effective.

Equally, the human side must not be disregarded. In many respects, it is the more important, as support for change or advancement can only be secured when the peoples concerned are convinced that such change will be for their advantage and worth the effort. Education has an important part to play here.

To the majority of the colonial peoples, agriculture is the foundation of their lives, their well-being and their hopes. With good will and understanding and with proper organisation, agricultural production can make great strides forward, but the traditions and customs of the colonial peoples must always be regarded sympathetically and with understanding. If the objective of greater production is made clear, enthusiasm aroused and willing co-operation secured, progress is certain. There are hazards which have to be surmounted, but with the aid of science, these will be overcome, and in future years they may be regarded as having been only the 'whistle points' along the track of development and progress.

AIRCRAFT ATTACK ON LOCUSTS

By Dr. D. L. GUNN

Anti-Locust Research Centre, London

THE most commonly effective method of destroying locusts at present is to poison the hoppers (nymphs) before they can fly. Some kind of bait, such as moistened bran, which is eaten in preference to other food, is poisoned with benzene hexachloride (hexachlorocyclohexane, 'Gammexane', 'Benhex') and is scattered thinly in front of the advancing bands. For an infestation of any magnitude, this requires a large labour force. In some parts of the world, even in Africa, there is a severe shortage of labour, so that it is increasingly difficult to get adequate supplies of casual seasonal workers. When a widespread plague occurs, it is sometimes necessary to call upon the army to do much of the work. In addition, the work must often be done in areas which are so far from sources of supply of food and even water that the cost of transport becomes considerable. It is therefore not surprising that attention has been given to the use of machinery to replace much of the unskilled labour.

The aeroplane is the machine which is most independent of difficulties of terrain, such as occur in the great spaces of Africa. One therefore naturally thinks of the aeroplane as the primary weapon for coping with inaccessibility of locusts and with mobility of migrating swarms; such a weapon would be especially valuable if the adults could be attacked before breeding. A number of attempts have been made during the past decade or so to use aircraft for attacking various kinds of insects; in few cases does it appear that these have led to the establishment of routine methods. The exceptions are mostly concerned with dusting or spraying particular places, so that a small airstrip can be cleared very close by, and light aircraft can attack day after day and year after year.

Much more difficult problems arise when the target is as mobile as a swarm of locusts. From time to time, aircraft trials against locusts have been made in various countries, usually with much optimism but with too little scientific background research to enable much to be learnt. These sporadic and disconnected trials have received newspaper publicity out of proportion to their real value. We have therefore set out systematically to find whether aircraft methods are applicable to locust destruction, and to work out where and when they may compete in effectiveness and in cost with other methods. This article is a summary of as yet unpublished material obtained in work initiated by the Anti-Locust Research Centre on behalf of the Colonial Office, and carried out in co-operation with the Royal Air Force, the Middle East Anti-Locust Unit, the East African Anti-Locust Directorate, the International Red Locust Control Organisation, the South African Air Force and the Union Department of Agriculture (Locust Control and Research Section), the Colonial Office Insecticide Flight, and perhaps most important of all, the Ministry of Supply, especially the Chemical Defence Experimental Station at Porton, Wiltshire.

The first experiments were carried out in 1944, by the Anti-Locust Flight (R.A.F. and S.A.A.F.) and Dr. J. S. Kennedy in the Kenya Highlands[1]. It was found that the most effective contact locusticide available was dinitro-*ortho*-cresol[2] (*D.N.O.C.*), and a dust containing 14 per cent of this was scattered from Avro Anson (Mark I) aircraft on to the locusts (*Schistocerca gregaria* Forsk.). The apparatus and methods were derived from the Russians, with whom the Flight had been preparing the work in Persia. It was found that the effectiveness of the dust varied enormously, apparently with atmospheric humidity, so that in wet conditions a high mortality occurred with less than 7 lb. of dinitro-*ortho*-cresol dust per acre, while in dry conditions there was a low mortality with more than 60 lb. per acre. The aircraft had to fly very low—below the tops of the occasional trees—to get the dust down relatively evenly in the right place, so that the swaths were narrow (7–25 yards), and the locusts were often disturbed and avoided the dust. The hastily improvised apparatus was heavy, it increased the air resistance of the aircraft, and it required a man in the aircraft to operate it, so that the useful load carried was only 650 lb.; consequently a single load would cover only twenty acres or so at a middling dosage, and even that took rather a long time. The mobility of a swarm caused very great difficulties, for it had to be located, its limits found, markers placed to guide the aircraft on each run, and the attack had to be completed between the time when the swarm went to roost in the evening and its departure a few hours after daybreak next morning. Further research was thus required on the insecticide and its distribution, on locust behaviour and on field organisation and methods.

Dr. Kennedy then returned to England, to the Ministry of Supply's laboratory at Porton, and began laboratory studies on the spraying of settled and of flying locusts with contact poisons, in close relation to his field experience[3]. These investigations covered the study of the dose required to kill an individual locust, the amount of spray which a locust would pick up under various conditions at rest and in flight, the effectiveness of poison falling on various parts of the body and the area dosage required in the field; they were, in fact, partly fundamental investigations on the principles of insecticide application, and have since been continued by others at Porton. A 5 per cent solution of *D.D.T.* was found to be ineffective at 9 gal./acre, while a 2½ per cent solution of dinitro-*ortho*-cresol in a mixture of aliphatic fractions of petroleum produced 50 per cent mortality at about 1½ gal./acre. Benzene hexachloride was less effective and slower in its contact action, which contrasts markedly with its superiority as a stomach poison for locusts.

By August 1945, a programme of spraying trials against locusts in Kenya had been prepared at Porton. The methods recommended, instead of being hindered by all except a narrow range of air conditions, were to take advantage of the wind in a calculated way so as to produce a wide and predictable swath. The solution was to be released from a single simple orifice placed outside the wash of the propellers, so that it broke up into drops in comparatively constant conditions; with a solution of constant physical properties, the drop spectrum could be determined and the way in which the drops would fall in ideal conditions could be calculated; inferences could then be made for applying the spray in real conditions. Methods of determining the proportion of the poison reaching the ground were worked out.

In early 1945, I was seconded from the University of Birmingham to the Anti-Locust Research Centre

The Commission emphasizes the need for a good library, though it will probably inevitably be a small one. The need for carefully considered medical arrangements, including a sick-bay for students, is fully discussed. A warden in charge is recommended; but a vice-warden is not considered essential unless the hall accommodates more than 150 students. Members of the university or college staff should not be admitted as residents unless they are prepared to assist in the creation of an academic and friendly atmosphere. Domestic administration should be in the hands of a bursar; it should not be left to the warden. General opinion favoured 100–150 as the most satisfactory number of students; though there are arguments for smaller units, mainly on grounds of congeniality.

The Report will prove of considerable value to academic and other authorities who are considering constructing halls of residence, and those who are interested in halls already in existence will read it with profit. Literary quotations in a factual report of this sort seem out of place; in fact, that introducing the index is fatuous.

Amalgamation of Instrument Makers: Hilger and Watts, Ltd.

The well-known instrument makers Messrs E. R. Watts and Son, Ltd., and Adam Hilger, Ltd., are being formed into one company registered as Hilger and Watts, Ltd. Watts was founded in 1856 and has specialized in the manufacture of surveying and engineers' measuring instruments, while Hilger, started in 1874, has built up a world reputation for instruments for research and industry. The products of the two firms are complementary to some extent, and the instruments developed by Hilger for chemical, biological and medical research are closely related with the products of James Swift and Son, Ltd., microscope makers, who are a subsidiary of Watts. The resources for research which have been at the service of Hilger and Watts respectively, and to which their success has been largely due, will be combined. The board of directors of the new Company is an amalgamation of the boards of Hilger and Watts, namely, G. A. Whipple, who has been managing director of Watts and Hilger since 1939 and 1946 respectively (chairman and managing director); F. Twyman (technical adviser); Dr. A. C. Menzies (controller of research); D. R. Stanley (controller of sales); V. W. H. Towns (technical controller); R. H. Watts (assistant controller of sales). Hilger and Watts, Ltd., will employ 1,300 people in the six existing factories. A new factory in the Greater London area has been planned and approved.

Export Organisation for British Scientific Instruments

Scientific Exports (Great Britain), Ltd., Buckingham House, Buckingham Street, London, W.C.2, is a co-operative marketing organisation set up by a group of British firms specializing in the production of high-quality scientific and surgical equipment. Through its world-wide agency, customers will be able to obtain from one source a very wide range of the finest equipment available. For circulation abroad, the organisation is issuing an illustrated bulletin, the first number of the technical series of which has recently been received. The bulletin is intended to supply regular and up-to-date information of progress in the above fields, and will include detailed descriptions of products, techniques, and developments in the spheres covered by the manufacturing members of the group of manufacturers involved. The members introduced in the first number are Allen and Hanburys, Ltd., founded in 1715 and famous for their pharmaceutical products; Baird and Tatlock (London), Ltd., laboratory suppliers for more than fifty years; W. Edwards and Co. (London), Ltd., high-vacuum specialists; Adam Hilger, Ltd., founded in 1874 and specialists in spectroscopes and astronomical instruments; Hopkins and Williams, Ltd., who have been engaged in the manufacture of fine chemicals for nearly a century; W. Watson and Sons, Ltd., founded in 1837 and chiefly noted for microscopes; and E. R. Watts and Son, Ltd., established in 1857, and makers of theodolites, levels and other surveying equipment.

Animal Health in British Guiana

A report on British Guiana, by Prof. W. C. Miller, forming part of a survey of animal husbandry, feeding, management and veterinary services in the West Indies, has been issued as Bulletin 19A of the series "Development and Welfare in the West Indies" (Bridgetown: Advocate Pub. Co., Ltd. 10 cents). Reviewing the general position of livestock, Prof. Miller points out that the running of estate dairies in the coastal belt has great potentialities from the point of view of improved human nutrition and of the general improvement of the livestock reservoir of the Colony, and suggestions are included both for a Government ranch and for a breeding policy for two types of herds. Stress is laid on the great potential asset of the cattle ranches; and in addition to proposals for changing the character of the breeding stock in the hinterlands, the report discusses transport of meat by air and the establishment of an abattoir. Dealing with peasant-owned livestock, Prof. Miller regards prospects for dairying as reasonably good; but now that extension of livestock production has been started, more adequate provision for control of disease and for improving animal health by the formation of a properly constituted veterinary service is imperative. In Prof. Miller's opinion, the minimum effective service would consist of one deputy director of agriculture, stationed in Georgetown, with two senior veterinary officers, one on the coastlands and the other in the Rupununi; two veterinary officers, one on the coast and the other available for emergency work; one senior and two other animal husbandry officers, one of whom would be stationed in the Rupununi or other part of the hinterland. Technical staff would also be required in the veterinary laboratory now being equipped. There is already more than sufficient work to keep such a staff fully employed, and basic agricultural education is also required at all levels. In particular, Prof. Miller directs attention to the question of scholarships for higher training in veterinary science and animal husbandry for locally born persons, and to the desirability of arrangements for periods of study-leave for officers already in the service to be spent at institutes investigating associated or cognate problems.

Lundy Field Society

The first annual report of the Lundy Field Society, Lundy Island, shows that the year's working was more one of growth, exploration and experiment than of achievement. The total membership is now 127, of whom thirty-four have visited and worked on Lundy during the season. Most of the work already attempted has been concerned with the building up of ornithological records, although the difficulty of maintaining a Heligoland-type trap on Lundy has meant that work on birds so far has been mainly carried out by observation. The report contains a full list of the species recorded and also an account of various ecological surveys begun in different terrestrial and freshwater habitats on the island.

National Museums of Ceylon

THE Administration Report of the Director of National Museums for 1946 (Ceylon Government Press, Colombo, 1947) gives news of the commencement of museum reconstruction in Ceylon. The Colombo Museum was derequisitioned by the military authorities in January 1946 ; but although the Public Works Department had the building under repair, it was not until the following July that any part of it was fit for the return of some of the Museum's collections. In spite of this and other difficulties, however, it is recorded that when part of the building was reopened there were 22,128 visitors to it between December 20 and 30 of the same year. Reference is made in this section of the report to the requisitioning of show cases by the military authorities in 1942 ; of the 262 taken over, only 85 were returned fit for use. To replace those lost, orders have been placed with the Crown Agents to the sum of Rs. 91,950, while a further sum of Rs. 41,850 was assigned to the Government Factory Engineer "for building show cases locally, with what was left of the glass that was removed from the original show cases at the time of requisitioning". One is left wondering to what use military authority could have put museum exhibition cases that they suffered so much damage. A new south wing to the Kandy Museum is under construction, and what is left of the King's Palace will be converted into a part of the same Museum. A special strong room will house the Sinhala Regalia. The Ratnapura Museum was reopened to the public in April 1946, while the Jaffna Museum was expected to reopen in July 1947. Under the different museum headings, the report includes long lists of acquisitions made during the year under review.

Standardization of Micro-film Technique

BRITISH STANDARD SPECIFICATION 1371 : 1947 for microfilm, readers and reels has been produced in co-operation with the American Standards Association's Committee, and American standards about to be published will provide equivalents to B.S. 1371, so that microfilms made in Great Britain should be capable of satisfactory projection on a reader made in the Commonwealth or in the United States, and vice versa. The specification covers 16 mm. and 35 mm. microfilm readers and reels for processed microfilm, each in a separate section. The first section specifies the stock to be used, dimensions, method of winding, the leader trailer and title frame, as well as the arrangement of images and correct sequence of pages for convenient reproduction. Essential dimensions for microfilm readers are specified in the next section, as well as other features for satisfactory reproduction, including the type of lens and magnification and the limiting temperature for the film in the gate, a method of measuring which is described in an appendix. Dimensions and features of reels for processed microfilm are specified in the third section. Standardization along the lines indicated in this specification and the three forthcoming American standards should materially assist the satisfactory use of microfilm and its extension to further fields.

Growth and Nature of Egyptology

AT long last the University of Cambridge has a chair of Egyptology, and Prof. S. R. K. Glanville's inaugural address has been published (London : Camb. Univ. Press. Pp. 37. 1*s*. 6*d*. net). The subject has for some time been taught officially in London, Oxford, Liverpool and Manchester ; but although so late in the creation of a chair, Prof. Glanville directs attention to three eminent Cambridge men—C. W. Goodwin, E. A. Wallis Budge and Sir Herbert Thompson—who played a big part in the building up of the subject. Actually, it is owing to the generosity of the last of this trio that the creation of the present chair has been made possible. Prof. Glanville continues with a brief survey of the subject under the three headings : monuments, antiquities and writings. He concludes with a strong plea that Egyptology, although not of immediate use like engineering and medicine, yet has its place in the teaching of a great university; he ends with a quotation from Housman : "The pursuit of knowledge, like the pursuit of righteousness, is part of man's duty to himself".

Society of Engineers : Awards

AT the inaugural meeting for 1948 of the Society of Engineers (Inc.), the first award was made of the Simms Gold Medal, established under a bequest by the late F. R. Simms, for "a paper or lecture describing a new technical discovery, an outstanding invention, or the results of useful research work". The medal was presented to Mr. J. G. Milton for his paper on "Research and New Developments in Water Treatment". Other awards were as follows : Bessemer Premium to Mr. C. D. Mitchell, for his paper on "Prefabricated Pre-cast Concrete Structures" ; Nursey Premium to Mr. R. Cecil Smart, for his paper on "Industrial Organisation as a Factor in Productive Efficiency" ; Bernays Premium to Mr. Bernard Payne, for his paper on "Water Supply Engineering". Two other papers, namely, "The Engineer and the Law", by C. L. Boucher, and "Liquid Springs", by R. H. Bound, were of particular merit; but their authors, as members of Council of the Society, were ineligible for awards, and they were presented with certificates under seal. The new president of the Society is Mr. E. E. Turner, formerly chief engineer to H.M. Airship *R*.34, and an authority on high-speed engine lubrication.

Research on the Biochemistry of Brain Tissue

THE Rockefeller Foundation has given £9,000 for research at the Neuropsychiatric Research Centre at Whitchurch Hospital, Cardiff, for research on the normal and pathological biochemistry of brain tissue under the direction of Dr. Derek Richter. Whitchurch Hospital is one of the leading hospitals in Britain for the investigation and treatment of mental disorders, and a Neuropsychiatric Research Centre has recently been established for which the present grant has been made. The magnitude of the problem of nervous and mental disease in Britain alone is not generally recognized. There are more hospital beds occupied by mental patients than by all other diseases put together, and the annual cost of upkeep exceeds £12,000,000. Research on mental disease has been very much neglected in the past. The object of the work now being carried out at Cardiff is to find out more about the working of the brain and nervous system in health and disease, so that this knowledge can be applied to the treatment of mental disorders of every kind. The lines of research now in progress include biochemical work on the enzymes in the brain, and work using the radioactive 'tracer' technique. Clinical research is also being carried out on problems related to schizophrenia, epilepsy and senility.

Capper, Pass Awards for Metallurgy

Messrs. Capper, Pass and Son, Ltd., of Bristol, have offered the Institution of Mining and Metallurgy and the Institute of Metals £200 a year for seven years, to be applied as follows: (*a*) £100 a year for one or more awards for papers on some aspect of non-ferrous extraction metallurgy; (*b*) £100 a year for one or more awards for papers relating to some process or plant used in the extraction or fabrication of non-ferrous metals. Both awards are for persons engaged full-time in industry or practice. The Councils of the Institution of Mining and Metallurgy and of the Institute of Metals have appointed a joint adjudicating committee which will examine annually all papers published by both societies; no special applications should be made for these awards.

Scholarships at Foreign Universities, 1948–49

The British Council has been informed that scholarships for the academic year 1948–49 will be offered to students and graduates of British universities and colleges by the Governments of a number of foreign countries, including Belgium, Hungary, the Netherlands, Sweden (with the Swedish Institute for Cultural Relations) and the University of Teheran, Persia. The scholarships are normally intended for study on the postgraduate level. They cover in general the cost of tuition and maintenance and in some cases the cost of travel. Two scholarships have also been offered by the University of Cologne, and two by the University of Munster. Negotiations with the Control Commission are proceeding with regard to facilities for food and accommodation. Particulars can be obtained from the Controller of the Education Division, the British Council, 3 Hanover Street, London, W.1.

University of London

The following appointments in the University of London have been announced:

Dr. L. J. Audus has been appointed to the Hildred Carlile chair of botany tenable at Bedford College as from October 1, 1948.

Dr. Eric Boyland has been appointed to the University chair of biochemistry tenable at the Royal Cancer Hospital (Free) as from January 1, 1948. In 1935 he was appointed reader in biochemistry at the hospital.

The degree of Doctor of Science has been conferred on Sir Alfred C. G. Egerton, University professor of chemical technology in the Imperial College of Science and Technology.

Royal Institute of Chemistry: Annual Meeting

The annual general meeting of the Royal Institute of Chemistry will be held during April 15–17 in Birmingham; this is the first occasion since the Institute was founded that the meeting has been held in the provinces, and in honour of the occasion the Birmingham and Midlands Section has arranged a programme of scientific and social events. The Lord Mayor of Birmingham will give a civic welcome to the president (Mr. Roche Lynche). The programme includes an exhibition, "The Chemist in the Midlands", to be held in the Central Technical College, Birmingham, which will feature the training of the chemist, research, production, and the chemist and the public services. The exhibition will be open to the public. Prof. R. P. Linstead will give a lecture on "The Chemical Research Laboratory, Teddington"; and Prof. Maurice Stacey will speak on "The New Fluorocarbon Chemistry". Visits have been arranged to the University of Birmingham and the Barber Institute of Fine Arts, Messrs. Chance Bros. glassworks at Smethwick, and Messrs. Marston, Thompson and Eversheds brewery at Burton-on-Trent.

Announcements

Lord Brabazon of Tara has been elected president of the Royal Institution in succession to the late Lord Rayleigh.

A memorial ceremony in honour of Max Planck is being arranged by the Max Planck Society for the Advancement of Science, the Academy of Science at Göttingen, the University of Göttingen, and the German Physical Society in the British Zone of Germany, and will be held in the University of Göttingen on April 23 at 11 a.m. This date would have been Planck's ninetieth birthday.

An international symposium on the "Kinetics and Mechanism of Combustion and Ignition Reactions in the Gas Phase" will be held in Paris during April 26–May 1. This symposium is being organised by the Centre National de la Recherche Scientifique, with the assistance of the Rockefeller Foundation. Detailed information can be obtained from Prof. P. Laffitte, 12 rue Cuvier, Paris (5ème).

Dr. Risto Jurva has been appointed director of the Finnish Institute for the Exploration of the Sea.

Dr. Cyril J. W. Hooper has been appointed editor and general secretary of the Society of Dyers and Colourists. Dr. Hooper, who was born in London in 1913, received his education at Tottenham County School and the Royal College of Science, and eventually obtained the London degree of Ph.D. for work in physical chemistry. After some experience in industry, he became reader with Messrs. Charles Griffin and Co., Ltd., and recently he has been librarian and information officer in the Research and Development Department of Ascot Gas Water Heaters, Ltd.

A joint meeting of the British Society for the History of Science with the Science Masters' Association, the Historical Association and the Association of Women Science Teachers will be held on March 9 at 5 p.m. in the Lecture Theatre of the Science Museum, South Kensington, London, S.W.7, to discuss "The Place of the History of Science in Education". The speakers will include Dr. E. J. Holmyard (chairman); Dr. Sherwood Taylor; Mr. G. Fowles, formerly chairman of the Science Masters' Association; Mr. S. M. Toyne, chairman of council, Historical Association; and Miss L. E. Higson, secretary of the Association of Women Science Teachers, and there will be a general discussion.

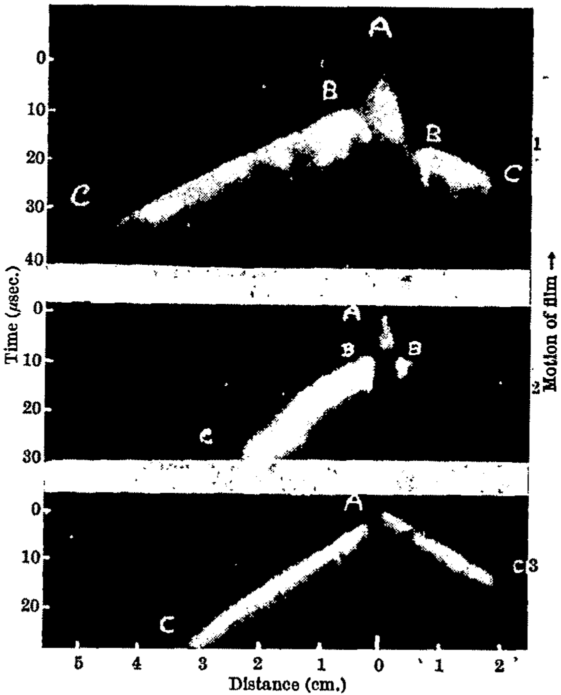
Birth and Growth of the Explosion in Solids Initiated by Impact

It has been shown that when liquid explosives such as nitroglycerine are initiated by impact, the explosion begins as a comparatively slow burning which spreads for a short distance from the point of initiation at a speed of *c.* 400 metres per second, and is then suddenly transformed into a faster propagation at *c.* 1,800 m./sec., which has the property of a detonation wave[1,2,3]. This two-stage propagation occurs when the initiation is caused by impact and compression of a small included bubble, or by sparking, and is observed with all the liquid explosives which have so far been investigated.

A recent study of the initiation of solid explosives by impact reveals a similar effect. If a thin film of the solid explosive is distributed on the anvil as an annulus, so that a small gas space is included during the impact, the sensitivity is increased[4]. Photographic experiments show that initiation begins at the gas space. This gives a convenient method of ensuring that the point of initiation is on the slit of the camera, and high-speed photographic studies of the growth of the explosion in the immediate vicinity of the point of initiation have been made both for secondary and for primary explosives. A typical result for a thin film of solid *P.E.T.N.* is given in Fig. 1. The initiation begins at *A* at the small included gas space, and the flame spreads from this point at a comparatively slow rate. In Fig. 1 this initial rate of burning (*AB*) is 450 and 300 m./sec. We should expect this rate to be dependent on film thickness, density of packing, etc., and in these experiments the rate varied from 100 to 600 m./sec. After a short distance (at the point *B*), this burning was transformed into a detonation, the speed of which varied from 1,000 to 2,500 m./sec. according to the density and film thickness of the explosive. In Fig. 1 this second stage (*BC*) is spreading at 1,620 m./sec. The transition from low-speed to high-speed propagation usually occurred at a physical discontinuity, that is, at the edge of the hammer, but this was not always the case. Films of cyclonite and tetryl gave similar results; but the initial burning was slower (100–300 m./sec.), and the thin film of explosive surrounding the hammer did not propagate.

A similar study has also been made of the initiation of primary explosives by gentle impact, both with and without added grit; when a grit particle was present, initiation began at the particle. The result for mercury fulminate initiated without grit is shown in Fig. 2. The two-stage propagation is again apparent. After initiation, the explosion spread for a short distance at a speed of 250–300 m./sec. before passing over to a high-speed detonation. Lead azide, on the other hand, usually showed no slow initial stage (see Fig. 3); detonation set in immediately unless extremely thin low-density films were used. It is interesting to note that for the *thermal* initiation of unconfined trains of these two primary explosives, Patry[5] found that fulminate gave an initial burning and azide did not.



1. *P.E.T.N.* FROM THE POINT OF INITIATION *A*, THE EXPLOSION SPREADS AS A SLOW BURNING *AB*, FOLLOWED BY A DETONATION *BC*. 2. MERCURY FULMINATE. SIMILAR TO 1. 3. LEAD AZIDE. NO INITIAL BURNING

A parallel series of experiments was carried out with thin films of *P.E.T.N.*, mercury fulminate and lead azide confined between two surfaces and initiated at the centre by a spark instead of by impact. The growth of the explosion initiated by the spark was very similar to that obtained by impact. *P.E.T.N.* and mercury fulminate both gave an initial slow burning which changed over to a detonation (the photographs were similar to Figs. 1 and 2). With lead azide, the burning stage was not observed and the photograph was similar to Fig. 3.

It is clear that for a number of solid explosives the first stage of the initiation by impact is a burning, and that the general behaviour is very similar to that observed in liquids under similar conditions. It is probable that under the impact, many explosives, particularly the softer ones, are compressed and flow like liquids. The results again suggest that, for solids as well as for liquids, the initiation under impact is essentially thermal in origin, and that the explosion begins at a hot spot which can be generated either by the adiabatic compression of a gas pocket, or by friction on a particle of grit, or (under extreme conditions) by viscous heating of the rapidly flowing explosive.

We thank the Royal Society for a grant for the development of high-speed cameras and the Ministry of Supply (Air) for other equipment.

Initiation of Explosives by Adiabatic Compression of their own Vapour

Previous work has shown that the sensitivity of liquid explosives to impact is greatly increased by the presence of minute gas bubbles[1]. The initiation is of a thermal nature and is due to the adiabatic compression and heating of the trapped bubbles. A simple method of including a gas space in an explosive is to spread it as a small annulus on a flat anvil. When this is struck with a flat hammer, the small amount of gas in the centre is trapped and compressed.

In these experiments the size of the annulus was such that the initial volume of the gas space was *c.* 5×10^{-5} c.c. With nitroglycerine in air at atmospheric pressure, regular explosions are obtained with an impact energy of 300–500 gm. cm. When the nitroglycerine is spread as a continuous film so that gas spaces are not present, very high impact energies are necessary (10^5–10^6 gm. cm.). At low initial air pressures (less than 10^{-5} mm. mercury), it is found that the annulus still exercises a similar influence in increasing the sensitivity, and explosions are still obtained with impact energies of *c.* 500 gm. cm. Although the other gases have been pumped out, the vapour pressure of nitroglycerine itself at room temperature is *c.* 10^{-3} mm. The experiments suggest that the initiation of the explosion under these conditions is due to the compression and adiabatic heating of the nitroglycerine vapour itself. This would assume that the vapour is not condensed during the rapid compression produced by the impact. The same high sensitivity is obtained when the evacuated space is filled with 50 mm. of methyl nitrate vapour, another explosive similar to nitroglycerine. This supports the above view.

These results have a bearing on the handling of liquid explosives. The compression of any small space, whether filled with a gas or with the vapour of explosive only, may initiate an explosion. Such a condition could arise, for example, during the collapse of bubbles formed by cavitation.

When a solid such as *P.E.T.N.* is distributed on the anvil as an annulus rather than as a uniform film of crystals, an increase in the explosion efficiency is again observed: the energy necessary to give an explosion efficiency of 50 per cent is $2 \cdot 8 \times 10^4$ gm. cm. for an annulus and $7 \cdot 1 \times 10^4$ gm. cm. for a continuous film. This increase in efficiency due to the annulus occurs both when the air pressure is initially one atmosphere, and when it is initially less than 10^{-5} mm. and the total pressure, including that of the explosive vapour, is *c.* 10^{-4} mm. Again, it would appear that the compression of the vapour of the explosive may initiate the reaction.

The behaviour of some solid explosives under impact thus shows many similarities to that of the liquid explosives. Apparently the air spaces which are present between the crystals of solid explosive are sealed off by local melting or plastic flow during the impact, and the adiabatic compression of the air or vapour in these gas spaces may initiate the explosion.

Acetylation of Sugars

The acetylation of sugars has hitherto involved the use of acetic anhydride and a catalyst such as sodium acetate[1], zinc chloride[2], sulphuric acid[3] or pyridine[4]. We have shown that glucose may be acetylated rapidly by means of a mixture of acetic anhydride and acetic acid if a small amount of perchloric acid is added to act as a catalyst[5]. No external application of heat is necessary to aid the reaction. By pouring the acetylation mixture into water, an almost quantitative yield of α-pentacetyl glucose is produced. This new procedure does not afford crystalline acetyl derivatives of galactose or mannose; but it works well for the acetylation of maltose, difructofuranose anhydride, α-methylglucoside, and polyhydric alcohols such as mannitol, sorbitol, erythritol, arabitol and pentaerythritol.

The method offers a rapid route to the formation of acetobromglucose and acetobrommaltose, inasmuch as the intermediate isolation of the acetylated sugars can be dispensed with and the acetylation reaction mixture treated directly with hydrogen bromide (cf. ref. 3). The advantages offered by this process arise not only from the fact that there is a great saving in time but also that the yields are improved. Thus acetobromglucose and acetobrommaltose, prepared as indicated above, give upon treatment in the usual manner with methyl alcohol in the presence of silver carbonate the corresponding tetracetyl β-methylglucopyranoside and heptacetyl β-methylmaltoside in yields of 55 per cent and 53 per cent respectively. Hitherto yields of 36 per cent and 24 per cent respectively have been recorded for the preparation of these glycosides by methods[6,7] involving the intermediate isolation of the acetates before treatment with hydrogen bromide.

A more detailed account of these experiments will be published elsewhere.

Paper Chromatography of Flavine Nucleotides

Partition chromatography on paper[1] has not hitherto been reported for the analysis of riboflavine, its nucleotides and derivatives. However, 'Collidine', and a butyl alcohol–acetic acid mixture (shake 4 parts butyl alcohol with 1 part glacial acetic acid and 5 parts water, and use the upper layer), are two very suitable solvents for separating various flavine compounds, identified by their characteristic green fluorescence in ultra-violet light, which will detect as little as 0·01 μgm. flavine on the paper. The separated substances can be easily and quantitatively removed from the paper by the method of Dent[2] and used for enzymic or other experiments.

Approximate R_F values. $\left(R_F = \dfrac{\text{distance moved by substance}}{\text{distance moved by solvent}}\right)$

	'Collidine'	Butyl-acetic
Flavine adenine dinucleotide	0·11	0·02
Riboflavine phosphate	0·09	0·09
Riboflavine	0·5	0·3

About 0·005 ml. aqueous, protein-free and salt-free flavine solution is required for the analysis. The homogenized tissue, flavoprotein, etc., is denatured (by boiling for three minutes, or standing at *p*H 2 and room temperature for five minutes), half its weight of ammonium sulphate added, and the protein precipitate centrifuged off. The free flavine is then concentrated by extraction into liquid phenol, and returned to water by addition of ether to the phenol layer. Since liquid phenol readily extracts proteins (hæmoglobins, cytochrome *c*, diaphorase), it is important to use protein-free solutions. Xanthopterin and leucopterin are also concentrated by this procedure; but their fluorescence on the chromatogram is quite different, and they do not interfere.

Examination of various tissues of the rat and rabbit (heart, brain, kidney, liver) shows only the presence of flavine adenine dinucleotide and some riboflavine phosphate, but no free riboflavine or other flavine derivative. Even after five hours autolysis at 38° C. of homogenized rabbit liver at *p*H 6·8, the flavine it contains is all protein-bound, and no riboflavin is produced. This suggests that there is no true storage of riboflavine as such in rabbit liver. Rabbit spleen homogenate, on the other hand, contains no flavine adenine dinucleotide or riboflavine phosphate, and added flavine adenine dinucleotide is rapidly broken down to riboflavine by an enzyme also present in acetone powder of spleen. This enzyme was also found independently by Comline and Whatley[3] at the same time.

In view of its sensitivity, this method seems very suitable for the analysis of enzyme prosthetic groups.

I would like to thank Dr. M. Dixon for suggesting and encouraging this work, which was supported by a grant from the Medical Research Council.

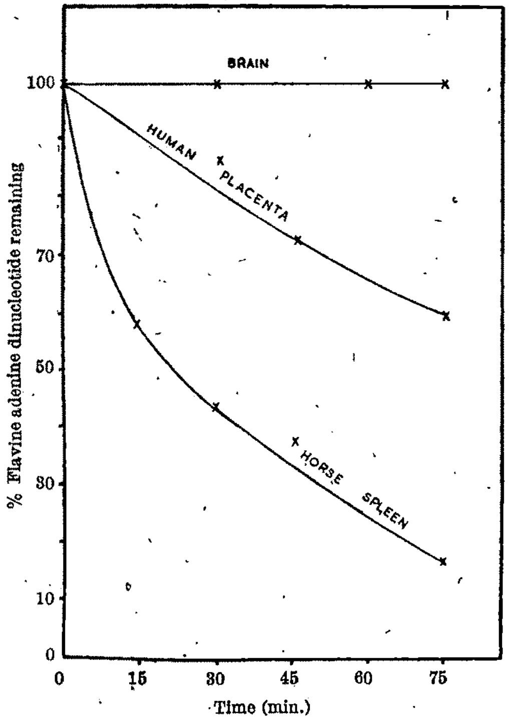
Inactivation of Flavine Adenine Dinucleotide by Tissue Extracts

RECENT experiments[1] on the synthesis of acetylcholine by tissue extracts, especially from acetone-dried brain, human placenta, and horse spleen, have shown that flavine adenine dinucleotide probably plays an essential part. It was found that spleen extracts only formed small amounts of acetylcholine under conditions giving a large synthesis with brain and placental extracts. Saline extracts of acetone-dried spleen, however, were found to contain a powerful inhibitor of acetylcholine synthesis. The effect of the inhibitor, which has the properties of an enzyme, was counteracted by adding large amounts of flavine adenine dinucleotide. This suggests that the inhibitor is an enzyme which breaks down flavine adenine dinucleotide; the action of tissue extracts on the dinucleotide has therefore been investigated in more detail.

Samples of flavine adenine dinucleotide were incubated at 37° C. for varying periods with saline extracts of acetone-dried guinea pig brain, human placenta or horse spleen. The samples were then placed in a boiling water-bath for 45 sec., cooled, and the coagulated protein centrifuged down. The flavine adenine dinucleotide content of the supernatant was estimated with a preparation of *d*-amino-acid oxidase protein from which the prosthetic group (flavine adenine dinucleotide) had been removed[2].



Flavine adenine dinucleotide was rapidly inactivated by spleen and more slowly by placental extracts; in contrast, brain extracts had no effect under the same conditions. This is illustrated in the accompanying graph. The optimum *p*H for the inactivation of the dinucleotide by spleen extracts was found to be about *p*H 7·2. After incubation for 75 min. with spleen extracts, the dinucleotide solutions had no effect on the synthesis of acetylcholine by human placenta.

These results may help to explain why brain extracts, in contrast to placental extracts, do not require a further addition of flavine adenine dinucleotide for maximal synthesis of acetylcholine. Spleen extracts, which rapidly inactivate the dinucleotide, only synthesize acetylcholine to an appreciable extent on the addition of very large amounts of the flavine adenine dinucleotide.

The presence in spleen of an enzyme breaking down flavine adenine dinucleotide was also shown at the same time by Crammer[3], using chromatographic methods.

Extracts of horse spleen did not reduce the oxygen uptake of unsplit *d*-amino oxidase, even after incubation for 1 hr. at 37° C. prior to adding the alanine; in addition, the splenic extracts did not prevent the reactivation of split *d*-amino-acid oxidase protein when added, together with flavine adenine dinucleotide, immediately before measurement of oxygen uptake, provided the spleen and the dinucleotide had not been previously incubated. This indicates that in the amino-acid oxidase system, the dinucleotide is not present to any considerable extent in the free state, but is bound to the oxidase protein.

From results on acetylcholine synthesis, it appears that the activator[4], which is another coenzyme required for this synthesis and which is probably identical with the coenzyme of acetylation[5], is also destroyed by spleen extracts.

These results will be fully described elsewhere. One of us (R. S. C.) has a research grant, and the other (F. R. W.) has a research training grant, from the Agricultural Research Council.

New Amino-Acids in Bacterial Hydrolysates

As part of the programme in this Laboratory of studying the relation between a bacteriophage and its host organism, analyses have been made of the amino-acid contents of hydrochloric acid and barium hydroxide digests of *E. coli*. The methods used for this have been the partition chromatography of Consdon, Gordon and Martin[1] as modified[2] to yield quantitative results. The following known amino-acids have been identified in these hydrolysates: aspartic and glutamic acids, serine, glycine, alanine, threonine, valine, *iso*leucine, leucine, methionine, tryptophane, phenylalanine, tyrosine, proline, arginine, lysine and histidine. In addition, three weak spots, indicated by the letters *a*, *b*, *c* in Fig. 1, have been noticed which do not correspond to known naturally occurring amino-acids. Spots *b* and *c* have only been visible when concentrated hydrolysates containing *c.* 40 mgm. N/c.c. have been applied to the paper.

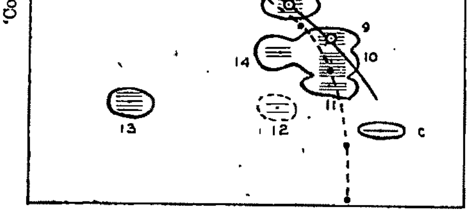

Fig. 1. TWO-DIMENSIONAL CHROMATOGRAM OF A 24-HOUR HYDROCHLORIC ACID DIGEST OF *E. coli* ORGANISMS IN *M* CRESOL + 0·1% AMMONIA AND 'COLLIDINE'

Aspartic acid, 1, glutamic acid, 2, glycine, 3, serine, 4, threonine, 5, alanine, 6, histidine, 7, valine, 8, *iso*leucine, 9, leucine, 10, phenylalanine, 11, tryptophane (present in barium hydroxide digests), 12, tyrosine, 13, methionine, 14, lysine, 15, arginine, 16, and proline, 17. The new amino-acids are *a*, *b* and *c*. The solid circles are the straight-chain amino-acids, and the open circles are the branched-chain compounds

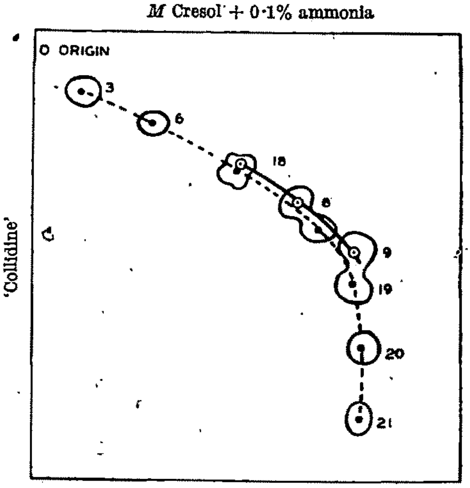

Fig. 2. TWO-DIMENSIONAL CHROMATOGRAM OF A MIXTURE OF ALIPHATIC AMINO-ACIDS

Glycine, 3, alanine, 6, α-amino *iso*butyric acid, 18, valine, 8, *iso*leucine, 9, *nor*leucine, 19, α-amino *n*-heptylic acid, 20, and α-amino *n*-caprylic acid, 21. The solid circle just below 18 is the position of α-amino *n*-butyric acid and the solid circle just below 8 is that of *nor*valine

Since Consdon, Gordon and Martin have shown that chemically related amino-acids occupy certain definite regions on a two-dimensional paper chromatogram, conclusions can be drawn regarding their probable identity. With the pair of solvents *M* cresol + 0·1 per cent ammonia plus a trace of cupron and 'Collidine' used in this work, the acidic, glutamic and aspartic acids occupy a region close to the origin. The basic arginine, lysine and histidine are in the top middle, while the neutral aromatic amino-acids tyrosine, phenylalanine and tryptophane are along the bottom of the chromatogram. Proline is an exception which, because of its high solubility in both organic and watery phase, forms a spot in the region of the bases. The neutral aliphatic amino-acids are regularly distributed. Whatever the pair of solvents employed, the straight-chain homologues of glycine and alanine always fall on a smooth curve. Branched-chain components of this series behave similarly, but their curves are slightly displaced. This is illustrated by Fig. 2, which is a tracing from a two-dimensional chromatogram of an artificial mixture containing the following substances: glycine, alanine, α-amino butyric acid, α-amino *iso*butyric acid, valine, *nor*valine, *iso*leucine, *nor*leucine, α-amino *n*-heptylic acid and α-amino *n*-caprylic acid.

Positions of the unidentified spots relative to the curves of the aliphatic amino-acids suggest that spot *c* may be due to a branched-chain isomer of α-amino *n*-heptylic acid. Spot *a* coincides exactly with that produced by α-amino *n*-butyric acid on a chromatogram of a standard mixture of amino-acids. Spot *b* lies in the region of the bases, but so far has not been identified.

There has been much controversial evidence about the occurrence of α-amino *n*-butyric acid in hydrolysates of proteins. It was reported to occur in alkaline hydrolysates of silk fibroin by Schützenberger and Bourgeois[3], but this was shown to be incorrect by Fischer and Skita[4]. Foreman[5] isolated a compound from casein which he believed to be this amino-acid ; but its melting point was lower than that reported for the synthetic product of Fischer and Mouneyrat[6]. Recently, Dent[7] has found it in the urine, blood and dilute acetic acid extracts of yeast.

Citric Acid in Semen

The discovery of citric acid in mammalian semen is due to Scherstén[1,2], who was also the first to point out that the acid originates in the accessory glands of reproduction, chiefly the seminal vesicles. In this respect citric acid resembles another more recently discovered component of semen, namely, fructose[3], which has similarly been shown to be secreted mainly in the seminal vesicles[4,5]. The present study was undertaken primarily with the view of investigating the possibility that there may exist a link between the two substances with regard to their formation, distribution or function in reproductive organs and semen. Citric acid was estimated colorimetrically[6,7]. The results were briefly as follows.

(1) Citric acid constitutes a major component of the seminal plasma. With the exception of the rabbit, it is usually absent from epididymal semen. It can be present, however, already in the ampullar semen (bull, ram), although in a much smaller concentration than in the whole ejaculated semen. A high concentration of citric acid in whole semen (mgm./100 ml.) is characteristic for bull (510–1,100), ram (110–260) and rabbit (110–550), all of which are distinguished at the same time by a high level of seminal fructose. It is, however, also present in boar (130) and stallion (55), which have a very low content of seminal fructose. On the whole, there is no correlation between the contents of citric acid and fructose, and the ratio between the two substances can undergo considerable fluctuations, even in the same individual. Occasionally, samples of semen are met with which contain only one but not the other component ; for example on two occasions we had the opportunity of examining samples of fish semen (*Scylliorhinus caniculus* which contained fructose but not citric acid. On th other hand, dog semen seems to be devoid of botl fructose and citric acid.

(2) The accessory organs of reproduction are th chief contributors of both seminal fructose and citri acid, yet the two substances can be shown to originat in different parts of the genital system. In rabbit, fo example, citric acid is met with principally in th glans vesicularis and is associated frequently witl the gel formation, whereas fructose is found in th highest concentration in the prostate organ[8]. A even clearer picture was obtained through the stud of the reproductive organs in the rat. The distributio of citric acid and fructose in the various parts o the reproductive system of the male rat is shown i the accompanying sketch, where it can be seen tha citric acid occurs chiefly in the ventral prostate an in the seminal vesicle, whereas fructose is foun mainly in the dorsal prostate and in the 'coagulatin gland', that is, the structure adjacent to the semina vesicle proper.

(3) Following castration, there is a remarkabl fall in the citric acid content of semen. In thi respect, citric acid resembles fructose[9]. However the post-castrate disappearance of citric acid is not s rapid as that of fructose. In rabbit, for example, th decrease may not become noticeable until three week after castration, whereas fructose has usually disappeared almost completely by the end of the secon week. Similarly, the reappearance of citric acid i response to testosterone usually follows some tim after seminal fructose.

(4) When fresh semen is incubated *in vitro*, citri acid disappears. The rate of disappearance, however is much lower than that of fructose. In bull an ram semen, for example, the rate of fructolysis[10] a 37° C. is 1·5–2 mgm. fructose/10^9 sperm cells/1 hour as compared with some 0·05 mgm. citric acid. Moreover, the rate at which spermatozoa metaboliz fructose is not affected by the presence of citrate On the other hand, the process of 'citricolysis' although very slow, may continue in semen for som time after the spermatozoa have exhausted the entir reserve of seminal fructose, that is, after the 'fructolysis' has come to an end.

(5) The observation has been confirmed tha mammalian spermatozoa contain aconitase and tha they are able to synthesize citric acid from oxaloacetic acid[11]. However, the bulk of the citric aci present in whole ejaculated semen is derived fro the seminal plasma and not from the spermatozoa It can be removed by centrifuging the seme and by washing the spermatozoa with Ringe solution. Citrate added to washed ram spermatozoa is incapable of maintainin the sperm respiration. In thi respect it differs from fructose a well as from many organic acid such as lactic, pyruvic, oxaloacetic acetic, propionic and butyric, al of which can maintain and prolong the respiration of washe spermatozoa.

This work has been carrie out on behalf of the Agricultura Research Council. We wish t acknowledge help and advice fro Prof. D. Keilin, Mr. J. Burkhardt

	Weight of organ (mgm.)	Citric acid (mgm./100 gm. tissue)	Fructose (mgm./100 gm. tissue)
Seminal vesicles	780	39	9
Coagulating glands	130	0	172
Median prostate	20	60	90
Ampullæ vas. def.	70	0	10
Dorsal prostate	250	20	82
Ventral prostate	320	122	0

The ultra-filtrate containing the inhibitors was divided into two portions, and carbon dioxide was passed through one of them. Equal amounts of the above two samples of the ultra-filtrate were added to two equal portions of the same enzyme solution, and it was found that the enzyme solution to which ultra-filtrate treated with carbon dioxide was added had a higher activity than the one treated with ultra-filtrate alone.

This clearly shows that carbon dioxide in some way neutralizes the action of inhibitors which are formed during the period of storage, thereby increasing the prothrombin activity of reversibly inactivated plasma.

In the accompanying table are presented the results of a typical experiment, using the same sample of plasma.

Treatment	Prothrombin activity (coagulation time)
Bovine plasma (fresh)	15 sec.
Bovine plasma (reversibly inactivated on storage) Before passing carbon dioxide	30 ,,
Bovine plasma (reversibly inactivated on storage) After passing carbon dioxide	15 ,,
Reversibly inactivated plasma (before ultra-filtration)	30 sec.
Ultra-filtered plasma	18 ,,
,, ,, + CO_2	17 ,,
,, ,, + ultra-filtrate	40 ,,
,, ,, ,, + CO_2	24 ,,

Our thanks are due to Prof. V. Subrahmanyan for his interest in this investigation.

Ovarian Activity in the Pregnant Mare

OVARIAN activity in the mare in early pregnancy presents some unusual features which are inconsistent with the accepted normal behaviour of the mammalian gonad during gestation. In the first place, the corpus luteum of pregnancy is very short-lived, and unlike that of most other mammals its period of activity would not seem to be prolonged much in excess of that of the œstrous cycle of the non-pregnant animal. Harrison[1] has observed that the corpus luteum of pregnancy completely fills the cavity of the ruptured follicle in four to six days and attains maximum size by the tenth to fourteenth day. Regression is stated[2] to occur at about the end of the first month. Secondly, follicular development is a common feature of ovarian activity at this time, and Day[3] has observed the occurrence of ovulation in a mare on the twenty-third day of pregnancy. Ovarian activity reaches its peak during the second and third month of pregnancy, when gonadotrophic hormone is abundant in the blood.

Ovulation of the many Graafian follicles which are brought to maturity by these hormonal means was recently doubted[4], but a more extensive search has now shown that it occurs in a high proportion of pregnant mares. To date we have recovered one or more ova from the Fallopian tubes of nine of fourteen mares which have been examined post-mortem when 46–73 days in foal. The ovaries of all these fourteen mares contained one or more fully formed corpora lutea; but in none, with the possible exception of one mare examined on the 46th day, could the primary corpus luteum of pregnancy be recognized. It is highly probable that during this stage of pregnancy a succession of follicles ovulate, from which corpora lutea are rapidly formed to maintain gestational requirements. Of the nine mares from which ova were recovered, ovulation had occurred in five from the right, in two from the left, and in the remaining two from both left and right ovaries. In all, fifteen ova were recovered, nine from the right and six from the left Fallopian tubes; three of the latter were found in one tube. The corpora lutea of the whole series were distributed in a proportion of 22 to 18 between the left and right ovaries. There is no reason, therefore, to suppose that the frequency of ovulation between the two ovaries is dissimilar.

Our observations on ovulation during the œstrous cycle, however, show that it occurred more frequently in the left ovary, and our findings are in close agreement with the extensive data of Kedrov[5]. We have palpated per rectum 24 mares during 45 cycles and have observed that of 36 single ovulations 22 occurred in the left and 14 in the right ovaries, and that of 9 twin ovulations 4 took place in the left ovary and the remaining 5 involved both ovaries. This greater activity of the left ovary is of interest especially in view of Kedrov's findings that implantation occurs more frequently in the right horn of the uterus. Last summer we examined, either post-mortem or by rectal palpation, the uteri of fifteen mares carrying single pregnancies, of which thirteen were implanted in the right horn. Only in four of these thirteen mares could we be certain that ovulation at the time of mating occurred in the right ovary alone. In another eight it was established that ovulation took place only in the left ovary. We have encountered twin pregnancy in five mares; in two of them the ovulation of two follicles was recognized, at the time of mating, as having occurred in the left ovary. Fœtal migration occurred in both mares; in one, a fœtus had become implanted in each horn, and in the other the right horn contained both conceptuses. In this small series of twenty pregnancies, fœtal migration had occurred in ten mares, the direction of the migration being in all instances from left to right. A high incidence of fœtal migration was reported by Day, but, unlike us, he observed its occurrence in both directions within the uterus.

We have undertaken preliminary investigations on the fertilizability of the ova which are discharged from the ovaries in early pregnancy with the ultimate object of inducing a second concurrent pregnancy and observing the course of secretion of gonadotrophin into the blood. Two pregnant mares in which mature follicles were palpable were injected intravenously with 1,500 I.U. of chorionic gonadotrophin and inseminated artificially with 20 ml. of stallion semen. They were examined four days later after they had been bled to death under anæsthesia. One was found to have aborted a twin pregnancy and no ovum was recovered from the Fallopian tubes. The other, which at the time of injection and insemination was about to ovulate from the left ovary and was pregnant in the right uterus, had not aborted; ovulation had occurred but the ovum recovered from the left tube had not been fertilized. Failure to effect fertilization in the latter mare is ascribed to the existence of a mechanical barrier to sperm migration presented by a non-patent cervix or by an encroachment of the fœtal sac into the non-gravid left uterine horn. It is hoped to exclude the latter possibility by repeating this experiment at an earlier stage in pregnancy.

Bile Acids of the Whale

As part of a general investigation into the nature of the 'bile salts' of vertebrates, we have examined the bile of a whale. So far as we know, no work on the 'bile salts' of cetaceans has previously been done. Through the kindness of Dr. M. Begg, of "Discovery" Investigations, we obtained bile from the fin whale (*Balænoptera physalus*): 3,000 ml. bile were collected from either the duodenum or the 'third stomach' of a single whale, and preserved with alcohol. The main biliary constituent has been found to be cholic acid, conjugated, apparently, chiefly with taurine. The chief 'bile salt' in this animal therefore resembles that of the teleostean fish, snakes and the majority of mammals so far investigated.

Production of Helium by Cosmic Rays

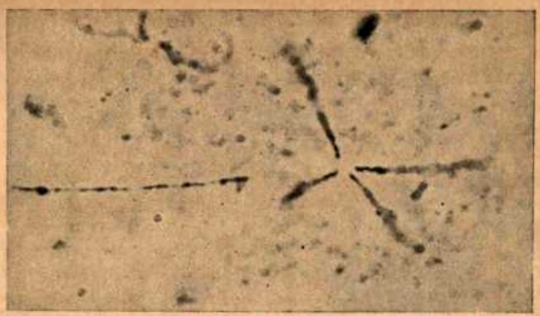
IN a recent experiment, a packet of Ilford's nuclear research plates (type $C2$) was exposed to cosmic rays for a period of six weeks at the summit of Mont aux Sources (11,000 ft.), Basutoland.

A preliminary examination of these plates has revealed several features of interest; the present communication, however, is concerned with one only of these, namely, the large number of nuclear disintegrations which occurred in the glass bases of the plates. These disintegrations become evident, of course, only when the product particles cross the glass surface and enter the emulsion. They then give rise either to a single track or to a 'star', which differs from a star originating in the emulsion in that its rays do not actually meet. The accompanying photomicrograph illustrates this.

The following classification summarizes observations over 4 sq. cm. of one of the plates. No disintegration is included which originates at a greater depth in the glass than 20 microns.

	2 rays	3 rays	4 rays	5 rays	Total
Number of stars	44	55	18	5	122

This is equivalent to a minimum of 15,000 disintegrations per c.c. of the glass. The great majority of the tracks appear to be due to α-particles, but if the conservative estimate of one α-particle per disintegration is allowed, the conclusion is that helium is produced in the glass at the rate of at least 10^5 atoms per c.c. per annum.



DISINTEGRATION OF A NUCLEUS WITHIN THE GLASS BASE OF THE PHOTOGRAPHIC PLATE. COOKE × 95 IMMERSION OBJECTIVE FOCUSED ON THE GLASS/EMULSION SURFACE

The chemical composition of the glass (by courtesy of Messrs. Ilford, Ltd.), excluding substances present in amounts of less than 1 per cent, is: SiO_2, 72; Na_2O, 14; CaO, 9; MgO, 3 per cent. Now these five elements, constituting 98 per cent of the glass, are among the most abundant and most widespread in the lithosphere. Oxygen, the most plentiful, accounts for 47 per cent of the earth's crust; silicon is next in order, with 28 per cent; calcium and sodium, fifth and sixth, with 4 and 3 per cent; magnesium, 2 per cent.

Rayleigh found that helium is present in almost all minerals. Its ubiquity has usually been ascribed solely to the presence of radioactive minerals throughout the earth's crust. The experimental results referred to above appear to indicate, however, that cosmic radiation may be responsible, first, for some part of the helium occluded in rocks, and secondly, for its widespread occurrence.

Estimates of the age of rocks and of meteorites obtained from measurements of the volume of helium occluded in them are based on the assumption that the helium is derived from radioactive minerals. If, however, cosmic radiation is also responsible for the production of measurable quantities of helium, then these estimates would appear to be unreliable in cases where the amount of helium is small. An example may illustrate this. The age of the Bethany meteorite[1] has been calculated as 100 million years on the basis of an analysis showing a helium content[2] (of radioactive origin) of 4×10^{-5} c.c. per 100 gm. But a short calculation shows that the helium produced by cosmic rays in the soda glass used in the Mont aux Sources experiment would amount to at least 2×10^{-5} c.c. per 100 gm. in the same geological period.

The estimate of the age of rocks by the helium method has always been reckoned to yield a minimum figure since helium diffuses so readily. If, however, a part of the occluded helium has been produced by cosmic rays, this 'minimum' will, in certain cases, need to be reduced.

My thanks are due to Prof. G. T. R. Evans, head of the Physics Department, for his personal interest in this research.

Phase-Contrast in Polarized Light

In a recent communication, Hartley[1] indicated a simple arrangement for realizing phase-contrast in polarized light. It consisted of a quarter-wave plate cut in two and reassembled after 90° rotation, so that the dioptric rays and the diffracted rays, crossing respectively the two parts of the plate, are changed in phase with respect to each other. This same method was indicated by one of us[2] at the international conference of the Institut d'Optique, Paris, held in October 1946, and its efficiency has been tested since by experiment. We tested also another design which has the advantage of giving the exact phase-change needed and independently permits the weakening of the dioptric rays in a continuous manner so that it can be adjusted to optimum intensity. (In the last paragraph of his letter in *Nature*, Hartley indicated a modification of his design in order to obtain also the weakening of the dioptric rays; in doing so, however, the correct phase retardation given by his first arrangement is lost.)

Our system is based on the following principle. The incident light is polarized by a 'Polaroid' screen before crossing the object. In the conjugate plane of the light source (which was a rectilinear slit in our experiment but which could have any other form, like a ring) there is a half-wave plate followed by a quarter-wave plate. The half-wave plate is cut into three, and the part to be crossed by the dioptric rays is rotated 45° to the rest of the surface (Fig. 1). In this manner the diffracted rays, and the dioptric rays after crossing this composite plate, have their vibrations oriented at right angles to each other, without any modification in phase. In crossing the quarter-wave plate placed behind, the convenient phase change between them is then obtained. The analyser (another 'Polaroid' screen) isolates the vibration components parallel to its principal direction[3].

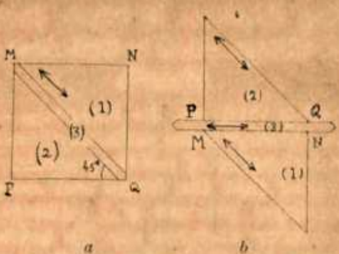

Fig. 1. (*a*) PLATE IS CUT INTO THREE PORTIONS, 1, 2, 3. (*b*) PORTION 3 IS TURNED THROUGH 45° AND INSERTED BETWEEN 1 AND 2

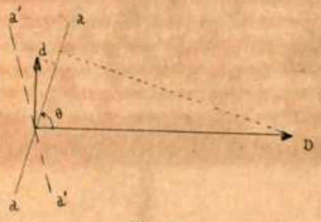

Fig. 2

Let D be the amplitude of the vibration in the dioptric rays, d that in the diffracted rays (Fig. 2) and θ the angle between the principal direction of polarizer (also the direction of vector D) and analyser. If $\theta = 90°$, the dioptric rays are suppressed and the system is equivalent to dark-ground illumination. If θ is less than 90° (position $a - a$ of the analyser) the resultant vibration will be: $D \cos \theta + d \sin \theta$, and the diffracted amplitude will add its effects to the dioptric amplitude. The system gives positive phase-contrast. If θ is greater than 90° (position $a' - a'$ of the analyser) the resultant vibration will be $D \cos \theta - d \sin \theta$ and the diffracted amplitude will be subtracted from the dioptric amplitude. We have negative phase-contrast. By rotating the analyser we can obtain zero intensity for $\cot \theta = d/D = \tan \varphi$.

If the diffracted light is produced by a small elevation of the object surface, the optical height z of this elevation will be given by the formula

$$z/\lambda = \frac{\varphi}{2\pi},$$

provided that $\varphi = \pi/2 - \theta$ remains a small angle.

In Fig. 3 are reproduced photographs taken for the three cases mentioned; the object is a piece of plain glass on which appears a line of transparent varnish $(1-1)$ and, crossing it, a small furrow made by a diamond point $(2-2)$. The composite half-wave plate used was cut in a fine 'Cellophane' sheet and imbedded in Canada balsam between optically flat glass plates. The quarter-wave plate was an ordinary $\lambda/4$ mica plate. The photographs were taken in monochromatic light (mercury 5461 A.).

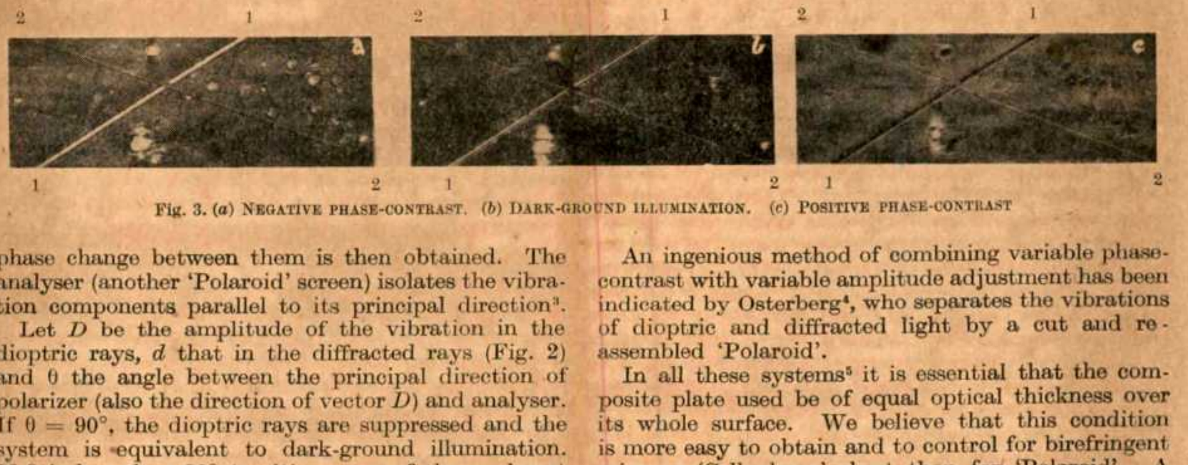

Fig. 3. (*a*) NEGATIVE PHASE-CONTRAST. (*b*) DARK-GROUND ILLUMINATION. (*c*) POSITIVE PHASE-CONTRAST

An ingenious method of combining variable phase-contrast with variable amplitude adjustment has been indicated by Osterberg[4], who separates the vibrations of dioptric and diffracted light by a cut and reassembled 'Polaroid'.

In all these systems[5] it is essential that the composite plate used be of equal optical thickness over its whole surface. We believe that this condition is more easy to obtain and to control for birefringent mica or 'Cellophane' sheet than for 'Polaroid'. A variable change of phase could be achieved in our design by replacing the quarter-wave plate by a Bravais compensator.

Recording Crevices in Plane Surfaces by Pigment-fillings Held in Cellulose Acetate Moulds

In extending work on the recording of low relief in etched or abraded plane surfaces of rocks, minerals and metals by means of cellulose acetate moulds[1], it has been found that the forms and distributions of narrow structural crevices and microscopic pits in these and similar surfaces can be accentuated, for detailed study, by filling them with a suitable pigment which is then removed by, and retained in, the thin cellulose acetate moulds made from these prepared surfaces (Fig. 1). For this purpose a dispersion of cellulose acetate in tetrachloroethane is convenient. Addition of an appropriate plasticizer to the dispersion minimizes the development with time of very slight shrinkage and brittleness in the resulting moulds.

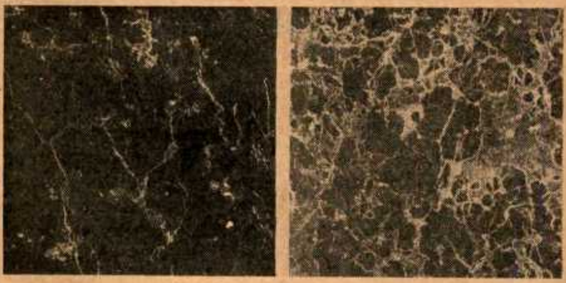

Fig. 1 Fig. 2

PHOTOGRAPHIC ENLARGEMENT (× 5/3) OF DYE-LINES ACCENTUATING 'RIFT' IN THE POLISHED SURFACE OF A GRANITE (FIG. 1) AND IRON OXIDE-AREAS EMPHASIZING CREVICES IN THE CRYSTAL FABRIC OF A POLISHED AND ETCHED IRON ORE (FIG. 2).

Each print was made from a cellulose acetate mould, thickness 0·08 mm., used in an enlarger as a 'negative' and employing Kodak *B.G.*-4 paper exposed to a 60-watt lamp for 15 sec. at *f* 8 for Fig. 1 and *f* 6·3 for Fig. 2.

This pigmentation method, foreshadowed in a previous communication[2], is distinct from the dyed resin impregnation technique of Dr. B. H. Knight. It is suitable for recording such features as rift and grain in granites, cleat in coals, inter-crystal fissures in well-crystallized rocks or metallic ores, and traces of cleavages, glide-planes, twin-boundaries or small shallow etch-pits in the surfaces of individual mineral crystals. Further, it may prove to be useful in studies of crazing on glazed pottery and the crystal fabrics of certain alloys. Experiments suggest the most satisfactory records obtained by this method are derived from crevices or pits varying in width between 1 μ and 10 μ.

The pigment can be a solid dye, such as 'Soluble Blue 3*M*' or lampblack, or a liquid such as Indian ink. If a powdered pigment is used, the etched surface is cleaned and sprinkled with either finely divided dye or lampblack, which is then introduced into the crevices with the ball of the thumb, or a pad of soft cloth. If Indian ink is employed, on the other hand, it is washed over the cleaned surface with a camel-hair brush, and the excess removed, after a moment, with a pad of absorbent cloth ; the use of cotton-wool is inadvisable as it tends to sweep cotton fibres into some of the surface crevices. Whether solid or liquid pigment is used initially, a careful rotary polishing movement with a suitable cloth removes it from the surface, while leaving it undisturbed in the crevices. The surface is then ready to receive the necessary thin layer of dispersion from which a pigmented cellulose acetate mould solidifies.

It is noteworthy that no significant spreading of pigment takes place in the dispersion-layer provided (*a*) the pigment used is not soluble in tetrachloroethane and (*b*) the dispersion-layer is thin. In connexion with (*a*), lampblack is a convenient pigment, apart from its relative chemical stability and its opacity in thin layers.

'Automatic' pigmentation of polished and etched surfaces of certain iron ores and iron-bearing meteorites[2] can be developed by exposing them to moist air for such a time that they become covered with thin films of hydrated iron oxides which can then be stripped from these surfaces in cellulose acetate moulds. By this means the forms and distributions of narrow fissures in the surfaces are recorded either as unpigmented bands, or as dark red-brown lines cutting the lighter brown limonite-bearing areas of the moulds (Fig. 2). Equivalent pigmentation can be obtained by developing thin films of copper carbonates on the polished and etched surfaces of some copper ores.

Finally, direct comparisons can be made between any pair of pigment patterns by superposing the necessary cellulose acetate moulds on an illuminated tracing desk, or by projecting them in a lantern or epidiascope, while photographic prints of any of the patterns can be made with ease by using the corresponding mould in the role of a photographic negative.

Photometric Measurement of Specific Surface

In the course of measurements of the light transmission of dispersions of fine alumina powder in aqueous media, it has been found in these Laboratories that the effective projected area per unit weight of the powder gives a fairly good straight line of negative slope when plotted against the fourth power of the wave-length of the incident light. The projected areas were calculated from the usual formula :

$$A = \frac{\log_e I_0/I}{KCt},$$

where A is effective projected area ; I_0 is intensity of incident light ; I is intensity of emergent light ; K is opacity factor of powder ; C is concentration of powder by weight per unit volume ; and t is path-length.

The measurements were made over the visible range with a photo-electric apparatus having a very low angle of acceptance (about 0·0001 ster radian), the opacity factor of the powder being assumed equal to unity. Extrapolation of the graph of A against wave-length to cut the axis of A yields a value of the projected area, A_0, for which the wave-length is very small compared with the particle size. In such cases it has been shown by Sinclair[1] that the effective projected area is equal to twice the geometric projected area A_G owing to diffraction and scattering.

The specific surface of particles in random motion is usually considered to be equal to $4A_G$, 4 being the ratio of surface to projected area for a sphere. However, the crystals of calcined alpha-alumina may to a first approximation be considered as flat rectangular plates, and hydrated alumina crystals are roughly cubical. It can be shown that the ratio of surface to projected area for a rectangular parallelopiped in random motion is $18\pi/(8 + \pi)$ independent of the relative lengths of the axes, that is, whether the particle is flat, cubical or elongated. If this factor is used to compute the specific surface of calcined and hydrated alumina from the values of A_0 ($= 2A_G$) found by graphical extrapolation, very good agreement over a wide range of samples is obtained with other estimates of the specific surface from air-permeability, sedimentation, and microscope data, if allowance is made for the flat shape of the calcined alumina crystals in the last two instances.

It thus appears that this method, which is rapid and economical of sample material, is capable of giving a good estimate of the specific surface of alumina powders over a wide range of values (1,000–40,000 cm.^{2}/gm.), and may find application to other transparent crystalline materials. The extrapolation method of evaluating A_0 seems to overcome the difficulty due to unknown variations in opacity factor with particle size.

If the Hilger Spekker absorptiometer, having a relatively large angle of acceptance, is employed for the measurement, the value of the specific surface has been found to be approximately $4A_0$, instead of $2{\cdot}55A_0$. This result is no doubt fortuitous, and may be ascribed to the fact that some of the light refracted or scattered out of the parallel beam by the particles is still capable of striking the sensitive surface of the photocell, thereby reducing the estimate of A_0.

It is hoped to publish a more detailed account of this work at a later date.

Luminescence Efficiency Changes in Zinc Sulphide Phosphors Below Room Temperature

At temperatures below those at which thermal quenching of luminescence occurs in zinc sulphide phosphors (as shown by the higher temperature forms of the curves of Fig. 1), there is often a slow temperature variation of the luminescence efficiency. The sign of the temperature coefficient of this variation may be positive or negative, being dependent on the wave-length of the exciting radiation. Typical efficiency temperature curves for a self-activated zinc sulphide phosphor are given in Fig. 1 for different excitation wave-lengths. This behaviour has been previously observed by Schön[1], and recently Williams and Eyring[2] have attempted to explain it in terms of the intrinsic luminescence centre configurations. Their treatment gives a slow rise in efficiency with temperature, of an exponential form for longer wave-length excitation; but it cannot explain the fall in efficiency with temperature at shorter wave-lengths.

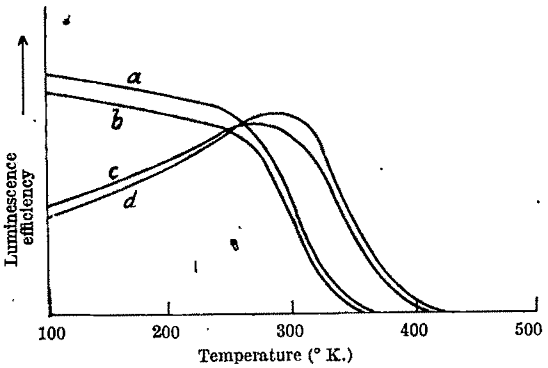

Fig. 1. LUMINESCENCE EFFICIENCY *vs.* TEMPERATURE VARIATION FOR ZnS–Zn PHOSPHOR. λ_{exc} FOR THE FOUR CURVES ARE: (*a*) 2537 A.; (*b*) 3132 A.; (*c*) 3653 A.; (*d*) 4043 A.

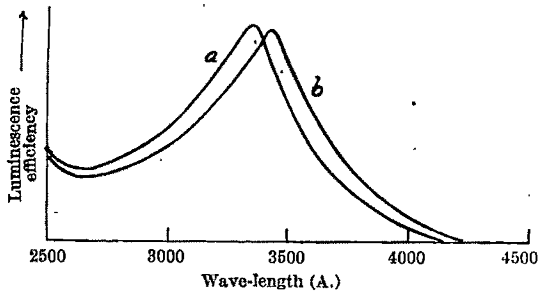

Fig. 2. EXCITATION SPECTRUM OF ZnS–Zn PHOSPHOR AT (*a*) 90° K., (*b*) 230° K.

We have made measurements of the excitation spectra, that is, the variation of efficiency of luminescence excitation with wave-length of the exciting radiation, of various specimens of zinc sulphide phosphors. In particular, studies of the change in these spectra with temperature have been made. Spectra measured at two different temperatures for a typical self-activated zinc sulphide phosphor are shown in Fig. 2. By comparison of the curves of Figs. 1 and 2, it is found that the temperature shift of the excitation spectra (Fig. 2) can account for the slow rise or fall of luminescence efficiency over the same temperature range at various wave-lengths (Fig. 1). We have measured the temperature shift in A./° K. of the excitation spectra of typical phosphors and find that it is the same as the temperature coefficient for the absorption edge shift in these phosphor types as measured by Gisolf[3]. A theoretical study due to Möglich and Rompe[4] has shown that the absorption edge shift with temperature agrees with that expected from the known thermal expansion of the phosphor crystal lattice.

The accompanying table gives a comparison of values for temperature coefficients of the absorption edge shift measured by Gisolf, and the shift of the excitation spectra from our measurements between 90° K. and 290° K.

		Temperature coefficients.
Phosphor	Absorption edge shift (Gisolf)	Excitation spectrum shift (our measurements)
ZnS–Cu	0·425 A./° K.	0·5 ± 0·05 A./° K.
ZnS–Ag	0·45 A./° K.	0·5 ± 0·05 A./° K.
ZnS–Zn	—	0·5 ± 0·05 A./° K.

It is concluded from the above experimental studies that the thermal expansion of the phosphor crystal lattice and its effect on the impurity centres responsible for emission, which are dispersed in the lattice, can cause the above efficiency versus temperature variations and their changes with wave-length of exciting radiation.

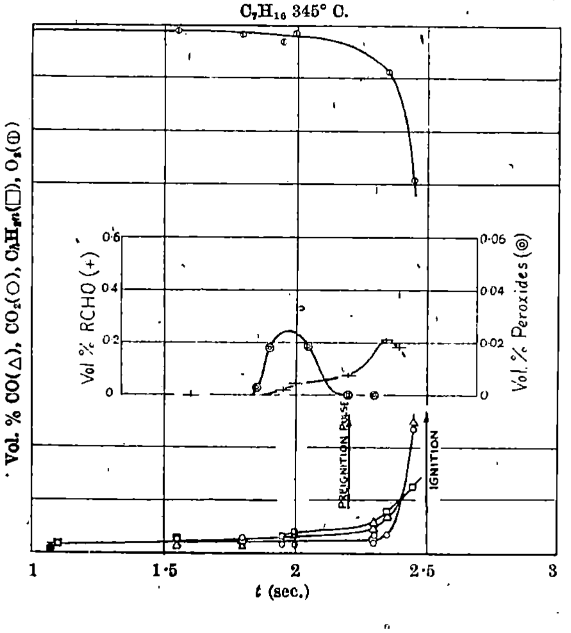
'Low-Temperature' Oxidation of Higher Hydrocarbons at Atmospheric Pressure

RECENTLY, we carried out ignition experiments in a Moore-type apparatus. Working between 300° and 500° C. at atmospheric pressure, we investigated the behaviour of *n*-heptane and an *n*-heptane–benzene mixture (50/50 by vol.).

With *n*-heptane, ignition was found to be preceded by a 'pre-ignition pulse'. The pulse could be observed by the expulsion of vapours from the apparatus or registered on a manometer connected to the apparatus. Three temperature regions could be distinguished. (1) Above 400° C., the delay between pulse and ignition was too short to be measured, so that ignition occurred apparently by a single-stage mechanism. (2) Between 316° and 400° C., the pre-ignition pulse was followed after a measurable time-interval by ignition. We measured both the time interval, τ_1, between the start of the reaction and the pre-ignition pulse, and the time interval, τ_2, between the pulse and ignition. In agreement with the observation of Sokolik and Jantovski[1], τ_1 decreased continuously with increasing temperature, while τ_2 passed first through a minimum and then through a maximum. (3) Below 316° C., no ignition could be observed, yet the pulse still occurred, down to a temperature of about 300° C., τ_1 increasing with decreasing temperature.

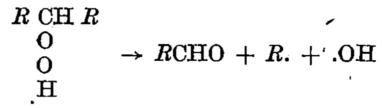
With the *n*-heptane–benzene mixture, again three temperature regions were observed: (1) above 425° C., ignition occurred apparently by a single-stage mechanism; (2) between 370° and 425° C. only slow oxidation occurred, without any physical manifestation such as a pressure pulse or ignition; (3) between 305° and 370° C. the pressure pulse occurred, without being followed by ignition. Only at 340° C. and pressures slightly higher than atmospheric was the pulse followed by ignition.

We collected gas samples corresponding to different stages of the reaction. The samples were analysed for oxygen, carbon monoxide and dioxide, unsaturated hydrocarbons, peroxides, aldehydes and oxides of nitrogen. The peroxides were determined with acid potassium iodide, sensitized with ammonium molybdate. Ferrous sulphate was ineffective as sensitizer. This leads us to the conclusion that the peroxides determined were of the alkyl hydrogen type[2], and probably secondary alkyl hydrogen peroxides. The concentration of oxides of nitrogen found was about 1 per cent of the concentration of peroxides, so that the measured value of the latter could be only slightly affected by the amount of nitrogen dioxide present.



A typical set of results, obtained for *n*-heptane at 345° C., is reproduced in the accompanying graph. Generally, we found that a peroxide maximum was followed by an aldehyde maximum, thus establishing the fact that aldehydes are products of the decomposition of peroxides. We found, further, that the pre-ignition pulse coincided with a decline of the concentration of peroxides.

We examined the experimental material in the light of existing theories. In agreement with the views expressed by Walsh[3], we concluded that initiation occurred through the formation of secondary alkyl radicals, leading to secondary alkyl hydrogen peroxide radicals and to secondary alkyl hydrogen peroxides. Decomposition of the latter according to



$$\begin{array}{c} R\,\mathrm{CH}\,R \\ \mathrm{O} \\ \mathrm{O} \\ \mathrm{H} \end{array} \rightarrow R\mathrm{CHO} + R. + .\mathrm{OH} \qquad (1)$$

seems to agree with the magnitude of the pressure pulse registered on the manometer.

The mechanism of the chain reactions following the pressure pulse is still a matter of conjecture, since no intermediate products have so far been isolated. We concluded that a combination of the reaction schemes proposed by Lewis and von Elbe[4] and by Ubbelohde[5] may present a reasonable explanation. At high temperatures, degradation reactions may prevail, RCHO decomposing according to the scheme proposed by Lewis and von Elbe, and $R^{\cdot}$, after peroxide formation, according to the scheme proposed by Ubbelohde. At lower temperatures, oxydialkyl peroxides may be formed, the decomposition of which leads to a branching reaction[4]. The tendency to follow slower degradation reactions at higher temperatures, as opposed to branching reactions at lower temperatures, would thus be responsible for the negative temperature coefficient of the overall reaction in the 'low-temperature' region.

Recently, Walsh[6] severely criticized the reaction schemes proposed by Lewis and von Elbe. The decomposition of secondary alkyl hydrogen peroxides is said to be responsible for the branching reaction, while the instability of the peroxide radical explains the negative temperature coefficient of the reaction. The evidence which we obtained during our experiments does not support this theory. At 316° C. with *n*-heptane we found a secondary alkyl hydrogen peroxide maximum, the decline of which was associated with a pressure pulse, yet no ignition (that is, a branching reaction) occurred at this temperature. We also found, for example, that the addition of tetraethyl lead to *n*-heptane did not suppress the formation of secondary alkyl hydrogen peroxides and the pressure pulses, but prevented ignition at temperatures at which it would normally occur with pure *n*-heptane.

It seems, therefore, that the chain reactions which follow the decomposition of the secondary alkyl hydrogen peroxides in the 'low-temperature' region still await a reasonable explanation.

A full account of our work will be published elsewhere.

Economy in Cell Counts

It is often necessary in clinical work to determine the relative abundance of two or more species of cells. Examples are counts of the percentage of atypical cells, such as reticulocytes, siderocytes or punctate basophilia, in the blood erythrocytes. In these cases the required result, F, is a fraction. If P and Q are the numbers counted of the two types of cell, $F = P/(P + Q)$. In other estimations, such as the 'platelet ratio', or the proportion of megakaryocytes to nucleated white cells in a marrow smear, the required result is a ratio, $R = P/Q$. F cannot exceed unity, while R may have any numerical value.

The frequencies of the two species of cells are often widely different, making it necessary to count thousands of the common type to include a moderate number of the rarer. The questions arise, Can one save time and labour by counting the abundant cells in a fraction $1/a$ of the area sampled for the rarer type? What would be the precision of a value of F or R so obtained? And what are the best values of P and Q to secure a desired precision with a minimum amount of counting?

There are various algebraically equivalent formulæ for the standard deviation of a ratio or a fraction. The forms most useful for the present purpose are

$$\frac{\text{Standard deviation of } R}{R} = \sqrt{\frac{1}{P} + \frac{1}{Q}} \quad . \quad (1)$$

$$\frac{\text{Standard deviation of } F}{F\,(1 - F)} = \sqrt{\frac{1}{P} + \frac{1}{Q}} \quad . \quad (2)$$

Now it can be shown that when P and Q are sampled on different scales, so that $R = P/aQ$ or aP/Q, and $F = P/(P + aQ)$ or $aP/(aP + Q)$, formulæ 1 and 2 are still true and applicable. It can further be proved that, for any given value of the standard deviation, the number of cells required to be counted is a minimum when $P = Q$. Hence the simple practical rule: choose that value of $1/a$ which will make the counts of the two kinds of cell as near equality as possible.

It is easy to see the commonsense justification of this rule. There is no point in laboriously measuring Q to an accuracy of 1 in 1,000 when P is accurate only to within 1 in 10.

When there is a big disparity in the frequencies of the two kinds of cell, the time saved by this method of 'balanced sampling' is very great. For example, in blood containing 2 siderocytes per 1,000 red corpuscles, a count of 80 cells by balanced sampling will give an answer as precise as a direct count of 10,000 cells. In general, if a is chosen to make $P = Q$, the total number of cells to be counted in balanced sampling is the fraction $4a/(a + 1)^2$ of the number needed in a direct count, for the same precision of estimate.

This method has the further advantage that a count of a given size always yields an estimate with approximately the same relative precision. One can therefore work out once and for all the numbers to be counted for any desired limits of significance, and choose the appropriate size of count for each particular purpose. There will then be no need to calculate standard deviations and significances of differences separately for each estimate.

I am publishing elsewhere a full account, giving details of the practical use of the method in cell counting. It is obvious that balanced sampling has many other uses. The technique here described is a special application of a general theory of weighted and stratified sampling, to be published elsewhere.

Empirical Data on Hilbert's Inequality

It is known that

$$\sum_{1}^{\infty}\sum_{1}^{\infty} \frac{a_r a_s}{r + s - 1} \leqslant \pi \sum_{1}^{\infty} a_r^2,$$

π being the best possible constant, and it has recently been shown by H. Frazer[1] that

$$\sum_{1}^{N}\sum_{1}^{N} \frac{a_r a_s}{r + s - 1} \leqslant \left(N \sin \frac{\pi}{N}\right) \sum_{1}^{N} a_r^2.$$

Frazer's result, however, is not the best possible, as may be seen from the numerical data below, in which λ is the maximum value of

$$\sum_{1}^{N}\sum_{1}^{N} \frac{a_r a_s}{r + s - 1}$$

for a normalized vector a_r. We are indebted to the Royal Aircraft Establishment, Farnborough, and to Mr. Fairthorne for the computation of these data.

N	λ		
1	1		
2	1·267	591	879
3	1·408	318	927
4	1·500	214	280
5	1·567	050	691
10	1·751	919	657
20	1·907	134	681

Approximate relations of the form

$$\frac{1}{\pi - \lambda} = a \log (N + b) + c$$

can be obtained to fit these data, with errors at the most of 0·001 up to $N = 10$, but an error of 0·005 for $N = 20$. It is evident from the behaviour of the errors that the formula is incomplete.

The values of λ for all values from 1 to 20 are at present being calculated for us at the National Physical Laboratory. The results will be published as soon as available.

EARLY HISTORY OF THE ROYAL BOTANIC GARDEN, CALCUTTA

By Dr. D. CHATTERJEE
c/o Royal Botanic Gardens, Kew

A GENERAL account of the Royal Botanic Garden, Calcutta, has been given by Biswas[1], and some of the detailed incidents connected with the formation of the Garden are also available in the published papers by Anderson[2] and King[3]. The Calcutta Garden is perhaps one of the oldest gardens in Asia, and it is not generally realized that it was established by the Honourable East India Company as early as 1787, essentially for the purpose of increasing the commercial riches of the Company, and *not* for the advancement of botanical knowledge in India and elsewhere. It was cleverly planned by an army officer, and the proposal was so attractive to the directors of the Company that they readily agreed to the establishment of such a garden. The detailed correspondence on the subject is preserved among the old records of the East India Company. This was made available to me through the courtesy of the Keeper of Records, India Office, London. Some of these letters have been published both by Anderson[2] and King[3], and it is not intended, therefore, to re-publish them here. The remainder of the letters afford other valuable and interesting information, and the purpose of this note is to reveal some of the lesser known facts regarding the origin and development of this garden.

Unfortunately the exact date on which the Garden was started is not clearly known. Carey[4] says that it was started in March 1786—a statement which seems to be wrong from an examination of the correspondence, and which has been corrected by Anderson. Prior to the official sanction by the East India Company, part of the Garden existed around the country house of Lieut.-Colonel Robert Kyd. This plot of land formed the eastern part of the Botanic Garden after its formation and has been referred by Roxburgh[5] in connexion with a tree—*Garcinia cornea* Willd. The actual proposal for the establishment of a botanical garden near Calcutta was submitted to the then Governor-General (Sir John Macpherson) at Calcutta by Lieut.-Colonel Kyd on June 1, 1786[6]. It was clearly stated in this letter that the idea of establishing a botanic garden is "not for the purpose of collecting rare plants as things of mere curiosity, but for establishing a stock for disseminating such articles as may prove beneficial to the inhabitants as well as to the natives of Great Britain, and which ultimately may tend to the extension of the national commerce and riches". It was suggested that the proposed garden would grow teak for ship-building, various spices (such as cinnamon, cardamon, clove, black and white pepper and nutmeg) for sale in Europe, and other articles of commerce (such as cotton, tobacco, indigo, coffee, camphor, gum-yielding plants and tea). The proposal was duly supported by the Governor-General, who wrote by way of recommendation to the Directors of the East India Company, "the garden may be formed as a general plantation or nursery where the cultivation of the cinnamon and the different articles mentioned by Col. Kyd may be attempted". The cost of maintaining this garden was suggested by Kyd at the low figure of Rs. 150–200 per month[7].

Kyd derived this inspiration, which led to the suggestion of forming a botanic garden, possibly from two sources: (1) in the garden of the previous Governor-General (Warren Hastings), he found some flourishing cardamon trees growing, and also some natural seedlings which promised a "rising plantation"; (2) Kyd himself was a keen gardener and at that time collected and grew, in the compound of his country house at Salimar, many foreign plants of economic and horticultural value. He used to secure these plants from the captains of the Company's ships returning from voyages to the Far East. Hence, his own experience had convinced him that some of the spices of the East Indies could be grown in India. If this could be achieved, it would have a further advantage, namely, the Dutch monopoly of the highly prized cinnamon and other spices would be broken.

The Court of Directors, too, as clever business heads of a commercial organisation, were alive to the benefits of this scheme. In their letter of approval, dated July 31, 1787, they duly stressed among other things the cultivation of cinnamon. This portion of their letter runs, "The experiment respecting the cinnamon tree in particular must be made in different parts and soils of those extensive provinces in order to ascertain with certainty whether this spice can be produced in Bengal equal to that which grows on the island of Ceylon[8]. We are aware that by extending your experiment too far, the expenses may increase to an amount of which you may not at present have any idea. But so sensible are we of the vast importance of the objects in view, that it is by no means our intention to restrict you in point of expense in the pursuit of it. In the cultivation of cinnamon tree in particular, we foresee a great source of wealth to the Company and of population and opulence to the provinces under your administration. Most earnestly therefore do we recommend it to you to proceed in your endeavours to propagate this spice in different places, and that you avail yourselves of the abilities and zeal of Lieutenant-Colonel Kyd herein."

The next step was the selection of a site and the acquisition of the land. This presented some difficulties. In his letter dated August 10, 1786, Kyd said that he, in company with a Mr. Hay, examined a plot of ground on the western bank of the river in the vicinity of Calcutta. One area which seemed suitable was not available, as on inquiry from Mr. Jonathan Duncan, the revenue officer, Kyd learnt that the ground had been allotted to the followers of Tishore Lama of Tibet, and had been consecrated for religious purposes. Kyd had of necessity to forgo this plot and chose a second area where the fort of Muggah Tannah and the barracks of the Moorish garrison formerly stood. This fort fell to the British under the leadership of Clive at the time of recapture of Calcutta. It was then demolished by mining. The condition of part of this ground was stated to be "perfect wild, overgrown with brush wood and subject to the overflow of the tide". This ground was adjacent to a plot of land which Kyd already possessed, and where he had his country house with his garden. A portion of this area fell within the limits of the Burdwan district (the extended limit of that time), and the Burdwan land was acquired from the Zamindar by exchanging an equivalent portion of East India Company's land elsewhere. Other lands of the Company, measuring 148 *bighas*-9 *cottahs*, were given to the residents of the ground, to induce them to leave the area, and the amount of compensation granted to them for their huts and personal effects was Rs. 3,166/4/0.

Having obtained the ground, Kyd with 109 labourers started to dig a ditch round the plot of land and also erected a fence. The fence was necessary to exclude wild buffaloes, which frequently visited the area. The monthly cost of this work, excluding the bamboo fencing, amounted to Rs. 384/0/0, and the work must have taken several months, for we read in a letter of the Treasury Officer (Buxey), dated May 1, 1787, that Kyd has drawn "one thousand sicca rupees" for this purpose. This amount appears to be only an instalment.

Those readers who have visited the Royal Botanic Garden, Sibpur, Calcutta, will recall that the ditch made by Kyd still exists, and is fairly continuous around the Garden, even now. A part of the ditch, that is, the ditch which now separates the Bengal Engineering College from the Botanic Garden, existed earlier, as this ditch formed part of the boundary of the old fort of Muggah Tannah. The portion of land, east of this ditch, that is, part of the present area of the Bengal Engineering College, was Kyd's personal land. This was given (at least, the major part of it) to the Botanic Garden at the time of its formation (1786–87), and remained so until 1820. In that year the same portion was given to the Lord Bishop of Calcutta for the establishment of a College. It appears that this old ditch of Muggah Tannah thus formed a ditch of convenience at the time of handing away a part of the garden land for the purpose of Bishop College, and the same holds good as a good demarcating line even now. The original ground of Kyd's garden house was known under various names, such as Kyd's Garden, Royd's Garden, Barwell's Garden, and in 1819 as Metcalf's Garden.

The next stage was to lay out the Garden and to start the commercial plantation of cinnamon and other spices. In this, Kyd was unusually ambitious but he was never a botanist. These two facts led to the complete failure of the enterprise after a few years of experiment. His ambitious aspect is evident from the fact that he wanted to grow every desirable economic plant of every country in his Garden. By a voluminous correspondence with British agents in different parts of Asia, he secured an amazing variety of plants, such as Persian dates, Persian tobacco, Chinese tea, oranges, English apples, cherries, apricots, sandalwood from the Malabar coast, and other plants like black pepper, bread-fruit, and a number of gum-producing plants. All these were duly planted out; but, as was to be expected, most of them perished in the uncongenial climate and soil of Calcutta. The cultivation of teak was also abandoned for the same reason in later years[11].

Kyd's term of honorary superintendentship of the Company's Botanic Garden was not a long one. His failure to grow so many commercial and economic plants should not be regretted by the present botanists of India, as his success (if it could have happened) might have altogether changed the destiny of the Garden. It appears to me that by his failure he paved the way to a botanic garden, which in the hands of his able successor played a very important part in the advancement of Indian botany. The name of Kyd should, however, be remembered with reverence as the founder of the Calcutta Garden which was destined to become a botanic garden and not a cinnamon plantation of the tea-garden type, on which so much stress was laid from the beginning, and at every stage.

Kyd died on March 26, 1793, and was buried in the South Park Street Cemetery in Calcutta. Two years later a memorial was erected in the Botanic Garden and a marble urn was placed on it. The site for this memorial was selected by Roxburgh[9], and the inscription on the urn says, "To the honour of Robert Kyd, an officer of the army and founder of this garden; placed by A. K. 1795" ("Roberto Kyd, *mil. trib. horti foundatori posuit A. K.*, MDCCXCV"). The initials A. K. refer to his relation, Alexander Kyd, who was then a major in the Bengal Engineers, and who later constructed the Kidderpore docks.

Kyd was succeeded by Dr. William Roxburgh, who on November 29, 1793, was appointed the first salaried superintendent of the East India Company's Botanic Garden. It was Roxburgh who got a sanction of Rs. 15,000 to build quarters for the Superintendent. This house was completed after 1795, and Roxburgh's request for a further sum of Rs. 5,000 (presumably over-spent in building the house) was refused by the Company. This house is a three-storied building on the river-bank and is still occupied by the Superintendent of the Garden.

During and since Roxburgh's tenure of office, the Botanic Garden near Calcutta has attracted the attention of the scientific world, and the scientific study of Indian plants dates from his time. (A few years prior to Roxburgh, Dr. Koenig was in India. Roxburgh regarded him as an intimate friend and also his preceptor. Koenig was essentially a plant collector who sent his plants to Linnæus (father and son) and Retzius.) Roxburgh has been, therefore, rightly called the 'father of Indian botany'.

It will be easily understood that, under the direction of a man of science such as Roxburgh, devoted to the scientific study of Indian plants, the original aims of the Garden as emphasized by the directors of the Company were not followed. Much about the same time the East India Company was being gradually eclipsed by the British Government. This was being done through the provisions of Pitt's India Act, and as such the control over Roxburgh became less and less effective. This allowed him to carry on as he liked.

For official purposes, the date of actual sanction to the proposal of establishing a botanic garden by the court of directors of the East India Company (that is, July 31, 1787) should be regarded as the beginning of the Garden. Prior to this date only a part of the Garden existed around Kyd's country house, which was included later within the botanical garden compound in 1787. On the basis of this date, the Royal Botanic Garden, Calcutta (as it is now known), completed its 150th year on July 30, 1937, and this was celebrated in a fitting manner on January 6, 1938. The latter date was apparently fixed for the sake of convenience only, as many British and foreign men of science, including the Director of the Royal Botanic Gardens, Kew, happened to be present in India at that time.

The East India Company during the years 1786–87 governed the country, collected the revenue, and administered law and order. Yet constitutionally its position was like that of landlord under the Nawab of Bengal. The Company at that time was still a private trading company, and could not be regarded as a part of the British Government. Robert[10] says, "the constitutional relation between the Nawab of Bengal and the East India Company at that time was indeed complicated. The Company secured the administration of military power and criminal justice (*Nizamat*) from the Nawab, and the power to collect revenue and administer civil justice (*Diwani*) from the Moghul Emperor." The above statement clearly shows that the East India Company was actually ruling the country under the shadow of the Nawab of Bengal. The Nawab was relieved of this heavy responsibility, as he got annually more than 40 lacs of rupees from the Company as lease-money. This position was cleverly stated by Clive thus, "the Nawab had only the name and shadow of authority, yet this name . . . this shadow, it is indispensably necessary that we should venerate".

This relationship should be clearly understood, as this represented the last days of the Moghul period, a dark period of the East India Company, and the formative phase of the British rule. Unless this is understood, one is liable to assume that the East India Company really represented the British Government at that time.

TRACE ELEMENTS IN PLANT PHYSIOLOGY

UNDER the auspices of the International Union of Biological Sciences, a symposium on "Trace Elements in Plant Physiology" was held at Rothamsted Experimental Station, Harpenden, under the chairmanship of Prof. B. Nemec, of Prague, during November 5 and 6, 1947. Representatives from many countries attended.

The symposium was conducted in four sessions, at which fourteen short papers were read to introduce the subjects for discussion. The work in progress on trace elements under Drs. Winifred Brenchley and Katherine Warington at the Rothamsted Station was inspected at the end of the meetings.

On the evening of November 6 the members of the conference were entertained at an after-dinner function at the Rothamsted Laboratories by the Director, Dr. W. G. Ogg, and the staff of the Station, when the delegates met senior members of Rothamsted concerned with trace-element investigations.

The subjects presented in the papers for discussion covered a wide field and included items of current scientific interest and practical importance, and demonstrated the immense value of plant physiological studies in investigating problems of crop production and animal husbandry.

Prof. Nemec, in his opening address, outlined the development of methods of research on trace elements, referring in particular to the early water culture experiments of Sachs and the influence of Prof. Stoeckard, of Tharandt Forestry School, Saxony, on this pioneer work. He exhibited a sample of gold obtained from the ash of plants of *Equisetum palustre* grown on volcanic soils in Bohemia, and referred to the concentration of droplets of metallic mercury in the seed capsules of *Holosteum umbellatum* on some soils.

Prof. T. Wallace and Dr. E. J. Hewitt (Great Britain) outlined methods in use in trace-element research at Long Ashton. It was shown how visual methods can be applied to problems of deficiencies, excesses and relationships of trace elements in plant nutrition studies, and how the method can be applied to analyse the injurious effects of soil acidity. Dr. Hewitt described his technique for large-scale sand cultures by means of which he has been able to study problems relating to deficiencies of iron, manganese, boron and molybdenum. The various points of these two papers were illustrated by a comprehensive exhibit of photographs.

Prof. J. Lavollay (France) outlined his method for the determination of the coefficient of action of mineral nutrients and illustrated the application of the method to problems concerning magnesium nutrition, showing how yield is related not only to the supply of magnesium in the nutrient, but also to the total concentration of salts in the medium. He demonstrated the beneficial effect of phosphorus on the action of magnesium and the antagonism which exists between magnesium and potassium; also the similarity of action of potassium and rubidium.

Dr. D. I. Arnon's (U.S.A.) contribution concerned the criteria of essentiality for micro-nutrients, and he illustrated his points by reference to his investigations in California on the essential role of molybdenum in plant nutrition. He suggested as the three criteria of essentiality of any element: (1) the life-cycle of the plant cannot be completed if the element is omitted; (2) the action of the element must be specific; (3) the effect on the plant must be direct. The paper and the discussion revealed the great practical difficulties of establishing 'essentiality' for elements required only in traces; but nevertheless it was thought that refinements of methods might disclose the essential nature of further elements.

Points of special interest in trace element nutrition were discussed in papers by Dr. E. G. Mulder (Holland), Dr. J. Erkama (Finland), and Prof. H. Burström (Sweden). Dr. Mulder described experiments concerning the functions of copper and molybdenum in the metabolism of higher plants and micro-organisms, and also referred to the application of his results to field crops in the Netherlands. Copper is regarded as a catalyst of oxidation processes, and molybdenum has been shown to be necessary for the reduction of nitrate nitrogen in higher plants and for the fixation of nitrogen by *Azotobacter*.

Dr. Erkama in his studies has regarded the three elements iron, manganese and copper as comprising one unit, and has endeavoured to determine their relationships. Manganese seems to be antagonistic to both copper and iron, and reactions with manganese seem to take place mainly in the vacuole sap. Copper, it is suggested, is able to remove iron from the vacuole sap and to oxidize it in protoplasm.

Prof. Burström reported results on the action of manganese in roots. Manganese appears to catalyse nitrate reduction in roots, and in this respect it may have a similar function to molybdenum in some plants. His results show that in roots, nitrogen increases the length of cells, phosphorus is concerned with cell multiplication, while manganese appears not to affect the ultimate length of the root. Manganese may shorten the meristem region, and while increasing the rate of root elongation it also shortens the 'grand period' of growth. Manganese thus seems to have effects apart from those concerned with nitrogen. Arising from this paper, the differential effects of NH_4 and NO_3 with *Aspergillus*, excised roots and attached roots were discussed in relation to redox systems.

The practical application of trace element investigations to crop-producing problems was discussed in the contributions of Dr. L. Gisiger (Switzerland), Prof. F. Steenbjerg (Denmark), Dr. Marie P. Löhnis (Holland), Prof. E. A. Jamalainen (Finland), and Dr. D. Mulder (Wilhelminadorp; this last being communicated by Dr. Löhnis).

Dr. Gisiger described investigations relating to crop failures in Switzerland during the War resulting from over-liming associated with deficiencies of boron and manganese. From his experiments he concludes that the damage from excess liming is due to the hydrating action of the $OH^{\cdot}$ anion. Boron tends to counteract this effect by dehydrating action, this being an alternative hypothesis to the fixation of boron by lime action. The $OH^{\cdot}$ ion is regarded as causing the unavailability of manganese over an intermediate range of pH, availability increasing at low and high pH values. The range of low availability is similar to that shown by Quastel *et al.*, at which soil organisms are active in the oxidation of soil manganese.

Prof. Steenbjerg outlined the main problems of trace elements investigated in Danish agriculture. Iron and manganese deficiencies are common in horticultural crops and copper deficiency occurs in crops on the sandy soils of Jutland. Cobalt deficiency in cattle has also been recognized. Investigations have largely concerned deficiencies of manganese and copper. With manganese the problems differ for sands and clays, and soil methods have been devised for advisory purposes. Organic matter is an important cause of copper deficiency, and the availability is greatly influenced by preceding crops. Grass is regarded as important in mobilizing soil copper. The copper content of plants has been shown not to be an infallible guide in the diagnosis of copper deficiency, since when growth is severely stunted the total copper content of the plant material (as percentage dry matter) may not be unduly low. A characteristic S-shaped curve is obtained relating dry matter production and total copper content. Deficiency values occur up to the point of inflexion.

Discussion of this paper showed that many problems concerned in availability of manganese and its relations to other elements in plants, for example, Mn/N, require further study.

Dr. Löhnis described her researches on the toxicity of manganese to crops in acid soils in the Netherlands. *Phaseolus vulgaris* and *Vicia sativa* were found to be highly susceptible, whereas oats and strawberries were resistant to damage. Resistance to excess manganese and susceptibility to manganese deficiency (as shown by oats) cannot be explained on the simple basis of 'ease of absorption of manganese' from the soil, since some crops are susceptible (for example, *Phaseolus*) and others resistant (for example, strawberry) to both excess and deficiency of the element.

Prof. Jamalainen gave an account of the occurrence of deficiencies of boron, copper and manganese in crops of Finland. Boron deficiency is prevalent in sugar beet, swedes and apples, and occurs even on strongly acid soils, though the deficiency is accentuated by liming. Other crops affected are clover, celery, turnips and white mustard.

Copper deficiency is also an important problem, particularly on peats, but also on sands. Clay soils are less affected. Cereals, hay crops, potatoes and root crops have all responded to copper dressings.

As the soils of Finland are mainly acid, manganese deficiency is rare, though marsh spot of peas has been noted in Aland. The deficiency may occur on over-limed soils.

The contribution sent by Dr. D. Mulder concerned the occurrence of zinc deficiency in fruit trees in Europe and referred in particular to apples, pears and cherries in the Zeeland province of the Netherlands and to reported instances in apples in Hungary, Denmark and Switzerland. The Dutch examples occur on highly calcareous sands, and the deficiency can be cured by winter or summer sprays of zinc sulphate.

A novel paper of the symposium was contributed by Prof. L. Seekles (Holland), in that it referred to trace-element problems in farm stock. The contribution showed clearly the similarity in plants and animals of many of the fundamental problems concerned with trace elements. Thus in both there appear to be direct and induced (or 'conditioned') deficiencies, and relationships between elements may be of great importance. Moreover, as Prof. Seekles pointed out, trace elements are concerned with many linked series of enzyme reactions in plants and animals, and the breaking of these series at different points from different deficiencies may result in varied or similar pathological conditions.

At the conclusion of the conference, Dr. D. I. Arnon proposed that an endeavour should be made to adopt a term for universal use to replace the numerous current expressions used by different workers, namely, 'trace elements', 'trace nutrients', 'minor elements', 'oligo elements', 'spuren-elements'. He was prepared to suggest the term 'micro nutrient elements' as a basis for discussion and agreed to prepare a memorandum on the subject.

NEW ZEALAND DEPARTMENT OF SCIENTIFIC AND INDUSTRIAL RESEARCH

ANNUAL REPORT FOR 1946–47

THE twenty-first annual report of the Department of Scientific and Industrial Research, New Zealand (Wellington: Gov. Printer. 1*s.* 9*d.*), includes the Minister's statement, the secretary's report for the year 1946–47, reports of the various research committees and of the Cawthron Institute, as well as reports from branches and on research work at Canterbury and Massey Agricultural Colleges. The three main new activities noted by the secretary are the establishment of a Fuel Efficiency Service in an effort to reduce the consumption of coal in industry; the extension of the Information Bureau to deal more systematically with the exchange of information for scientific workers of the Department and the Dominion generally, and its dissemination among interested Departments and the public; and a start on the use of radioactive tracer elements in certain biological and chemical problems associated with soil processes. Building research included investigations on lightweight concrete and pumice concrete and the testing of properties of new materials, while the Plant Diseases Division examined the toxicity of wood preservatives and the treatment of infested buildings, as well as the testing of preservatives against fungi. The

Dominion Physical Laboratory undertook measurements of thermal transmittance on two types of concrete construction and also on a weatherboard house.

The work of the Dairy Research Institute was focused upon further improvement in the quality of New Zealand dairy products for export, reducing losses in manufacture, utilizing skim milk to the best advantage in feeding calves in New Zealand, and the influence of the plane of nutrition of the dairy cow during its normal dry period on the quality and quantity of milk produced in the subsequent lactation. The finding that cress-taint does not appear in the butter if cream from cows that have consumed cress is pasteurized below 180° F. was confirmed. Attempts were made to determine the relative influences of fat and casein on the moisture-holding properties of cheese-curd, while the Fats Research Laboratory established on April 1, 1946, initiated research on the nature of fats, particularly those occurring in dairy products.

Fruit cold-storage research covered the influence of root-stock and intermediate scion on core-flush in Granny Smith apples and the effect of a pre-harvest, fruit-fixing spray or superficial scald. Trials with 'Pliofilm' wraps in the shipment of oranges indicated that the percentage of sound fruit was substantially increased, but the high cost of the material outweighed the saving; use of paper wraps impregnated with diphenyl proved highly economic in reducing losses from fungous rots. Fruit research included manurial investigations and root-stock trials on apples, variety trials on apples, peaches and citrus fruit, investigations on codling moth control, tests on new products such as 'Gammexane', 'Dittane', 'Fermate' and 'Phygon', magnesium deficiency investigations, studies of the effect of penicillin on fruit fungi and of the control of black-spot of apples and pears with 'Elgetol' spray, raspberry investigations and a disease survey of orchards.

The Industrial Psychology Division made a survey of eye-strain in two clothing factories, and commenced an investigation into the adjustment of youth in industry as well as carrying out many vocational examinations. The Leather Research Association's studies of the quality of sole leather indicated that the wear life of a sole bears a definite relation to the amount of hide substance per unit area. Some of the fundamental properties of water-pigment finishes in use were examined, as well as difficulties experienced in curing and storing calf-skins. The Shoe Research Association commenced an investigation on the types of leather most suitable for insoles, and continued its work on the effect of perspiration on leather. The Fertilizer Manufacturers' Research Association drew up a programme of work and was selecting a site for its laboratory. The Pottery and Ceramic Research Association carried out preliminary work on the differential thermal analysis of New Zealand clays and completed preliminary work on a similar method, for determining free quartz in clays. The Woollen Mills Research Association continued its control work on unshrinkable finishes, as well as further trials of 'Gammexane' against carpet beetles, and completed the mill tests on the manufacturing trial of hairy wool and the combing trial of exported scoured wool.

Under the Tobacco Research Committee, fertilizer experiments led to a general increase in yield, magnesium having a beneficial effect on both yield and quality. Surveys were made of both mosaic disease and black root-rot in the seedling beds of many growers, and experiments to control collar-ro continued, while the Cawthron Institute continue soil mapping of tobacco lands. Other work at th Cawthron Institute related to land utilization, so analysis and investigations on tomatoes, includin the treatment of soil with steam, formalin an chloropicrin, the effect of cocoa-bean husks, compos etc., on yield, tomato 'cloud' and 'hard-core'.

Research work at Canterbury Agricultural Colleg included sheep-dipping trials with *D.D.T.* an 'Gammexane', studies in copper deficiencies, o insect pests of wheat crops and on subterranean clove as well as farm-machinery research, microbiologic investigations of ear blight and frost damage, eyespo disease, the efficiency of commercial seed-whe dusting and the seed disinfection of peas. At Masse Agricultural College studies on hairy sheep (N typ added to our understanding of the fleeces of bot hairy and non-hairy sheep. Other work was concerne with the propagation of cuttings, drainage and th internal parasites of sheep, while the Biochemistr Department studied the wear of sheep's teeth an the milk supply of Romney ewes.

Since the reversion of the control of the geophysic work at the Apia Observatory to the Departmen efforts have been made to provide modern buildin suitable for tropical conditions, modern equipmen adequate scientific staff and congenial living condition

The Auckland Industrial Development Labor tories report an increase in the number, variety an complexity of the industrial problems in whic assistance has been sought, while the first annu report of the Biometric Section indicates that, i addition to facilitating basic statistical and biometric control of agricultural trials, the Section was con cerned mainly with the collection of an adequa library of technical literature, the recruitment an training of staff, the exploration of methods, such a the punched card technique, of handling extensiv collections of data, as well as research and consultativ work.

At the Dominion Observatory the method of con trolling the standard clocks was unchanged, and th time-service arrangements were continued as pr viously, except for special time signals which had bee sent out for war purposes up to January 31. Th chief seismic event was the disturbance in the Lal Coleridge region on June 26; but 306 earthquak were felt during the year in some part of New Zealan 87 in the North Island and 219 in the South Islan

Lack of accommodation is still a great hindran to the work of the Dominion Laboratory where, i addition to the examination of 25,103 sample research was carried out on New Zealand woods, an special coatings were applied to experimental box in an effort to overcome the tainting of butter b boxes made of *Pinus radiata* timber. Much spectr graphic examination of metals was carried out f industry, and the Coal Survey Laboratory co-operate with the field staffs of the Geological Survey and th Mines Department in a continuation of the physic and chemical survey of the coal resources of th Dominion. Equipment on a pilot-plant scale for th production of penicillin and other antibiotics wa designed for installation at the Plant Chemistr Laboratory, and an experimental tray dryer was al designed and installed. A complete survey of a certified plant therapeutic compounds on the mark was also undertaken.

The Dominion Physical Laboratory has assiste many New Zealand manufacturing firms with tes on materials and equipment, the design and supply of special measuring apparatus, replacement parts for machinery and small precision tools, and about half the time of the Laboratory has been spent on similar work for Government Departments. Major investigations during the year included vacuum-pressure impregnation of timber with synthetic resins, the moulding of plywood, the thermal efficiency of open-hearth fires and the design and construction of micro-wave meteorological radar. In addition to its butter-fat investigations, the Fats Research Laboratory has used a molecular still of novel design for the preparation of fish liver-oil concentrates. In addition to vitamin analyses, the Plant Chemistry Laboratory has conducted a successful trial of new hormone weed-killers. Work under the Plant Research Bureau included an extensive breeding programme for garden peas and field peas, as well as for barley and other field crops. A vegetable research section was established, and the Botany Division made further surveys of vegetation and extended its collections of agar seaweed and of carrageen (Irish moss). The Grasslands Division carried out further work on pedigree strains of pasture species, blind-seed disease of rye-grass and soil conservation, while in addition to therapeutic testing the Plant Diseases Division studied tree-tomato mosaic, lettuce mosaic, halo-blight of beans, and soil disinfection. An investigation was also commenced on boron and its relation to the incidence of yellow leaf.

PHOTO-ELASTIC INVESTIGATION OF INTERNAL STRESSES IN SILVER CHLORIDE CAUSED BY PLASTIC DEFORMATION

By J. F. NYE
Cavendish Laboratory, Cambridge

INTERNAL stresses in cold-worked metals cannot be investigated fully by means of X-ray diffraction because in most cases the stresses vary considerably in distances comparable with the cross-section of the X-ray beam. For this reason, X-ray methods can indicate only the presence and magnitude of internal stresses, but not their distribution in space. A more powerful and direct method of approach is provided by the photo-elastic effect in transparent crystals. Cubic crystals are particularly suitable, since they are optically isotropic when unstressed; the magnitude and orientation of their birefringence, and its distribution over the crystals, thus give a direct picture of the distribution of internal stress. There is no reason at present for supposing that the plastic deformation of transparent crystals differs fundamentally from that of other crystalline substances, and one may reasonably expect that results derived from experiments on such materials will also be applicable to metals.

Since December 1946 a series of observations has been made on polycrystalline silver chloride, a material that is transparent, cubic in structure, and also very ductile. Rolled sheets, of thicknesses from 0·3 to 1 mm., supplied by the Harshaw Chemical Company of Cleveland, Ohio, showed patches of birefringence when placed between crossed nicols. These patches disappeared when strips cut from the sheets were recrystallized by heating for two hours at 400° C. and cooled slowly. (The melting point of silver chloride is 455° C.). Subsequent plastic deformation of such flat strips gave patterns of birefringence of which an example is shown in Fig. 1. This photograph was taken in white light between the crossed nicols of a polarizing microscope after unloading the strip; the polarization directions of the nicols are horizontal and vertical. Light areas indicate residual stresses. The pattern is not coloured because, with sheets of this thickness, the path differences due to the stress birefringence are smaller than the wave-length of light. The average width of the grains is large compared with the thickness of the sheet. Most of the grains are crossed by one, or sometimes two, sets of light and dark bands, similar to those observed in transparent single crystals by Brewster[1], by Reusch[2], and by Obreimow and Schubnikoff[3]. They appear to be the result of deformation by glide or by kinking[4]. Other interesting points are visible: for example, plastic distortion in grain *A* has evidently contributed to the stress pattern seen in the neighbouring grain *B*. When an external stress is applied to the strip the grains lighten and the progress of further plastic deformation can be watched. (I gave a demonstration of these phenomena at a conversazione held by the Royal Society on May 29, 1947.) A small portion of another strip is illustrated in Fig. 2, also photographed between crossed nicols; several intersecting sets of bands are shown. In Fig. 3 a grain boundary *XX* separates two grains, each of which is crossed by a particularly sharp set of birefringent bands, produced in this case by bending. The polarization directions of the nicols are again horizontal and vertical. If the nicols are turned through 45° the light stripes become dark and the contrast of the pattern is much reduced. Such observations combined with the use of a compensator make it possible to calculate the distribution of stress within the bands.

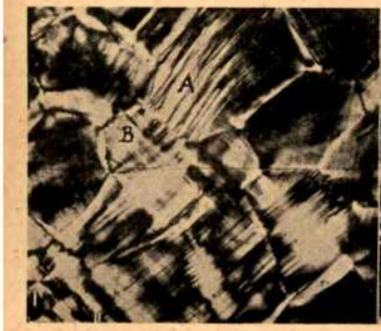

Fig. 1. × 13

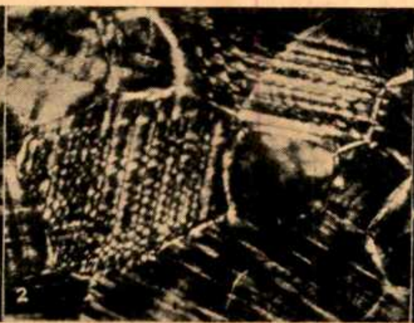

Fig. 2. × 25.

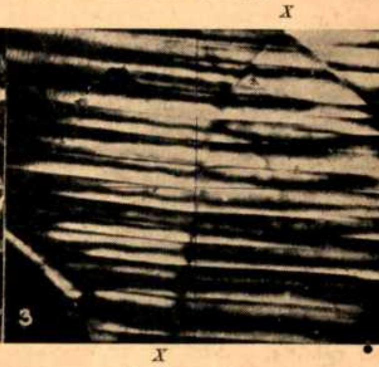

Fig. 3. × 41

Bands of a very similar nature have been reported in diamond by Raman and Rendall[5], and investigated in detail by Ramachandran[6]. These authors attribute the bands to the stresses set up in alternate layers of diamond having two different lattice spacings. It would be interesting to know whether they are not really the consequence of plastic deformation.

Examination of a plastically deformed strip of silver chloride that was annealed in stages shows that heating near the melting point causes a gradual reduction of the intensity of the picture, but leaves the pattern unaltered. We may conclude that, during annealing, there occur no large-scale migrations of dislocations, but only localized processes of atomic rearrangement.

Although they are optically isotropic when unstressed, cubic crystals under stress behave differently from glass and the usual plastics used in photo-elastic tests. The crystal classes T_d, O, O_h require not two but three constants to describe their photo-elastic behaviour, and, as has recently been pointed out[7,8], the T and T_h classes (also in the cubic system) require four. This fact makes the full interpretation of the stress birefringence pattern dependent upon a knowledge not only of certain combinations of these constants, but also of the crystallographic orientation of the grains concerned. It also leads to a striking phenomenon observed in the elastic stress range: when a bending moment is applied to an annealed strip, viewed either between crossed nicols or in a circular polariscope, the grain boundaries are seen to flash out brightly. The effect is completely reversible; if the load is removed the light regions return to their original dark state. The explanation seems to be that, when the bending moment is applied, the light passing through a grain traverses a layer of tension on one side of the strip and a layer of compression on the other side. The birefringence of the two layers cancels out, and the total path-difference between the two oppositely polarized rays will be zero. However, grains with different crystallographic orientations will have different stress-optical constants; consequently, whenever a grain boundary is not perpendicular to the sheet, rays crossing the boundary will pass through different grains on the tensile and compressive sides, and the total path difference will not vanish. In contrast to the grains themselves, therefore, the grain boundaries will be lightened. A more exact mathematical treatment of the effect is possible and its results are supported by other observations, but the above argument contains the essence of the explanation. Such bending moments cause the lightening seen at some of the grain boundaries in Fig. 1.

A fuller account of these and other photo-elastic experiments on plastically deformed materials, carried out with the financial support of the British Iron and Steel Research Association, will be published elsewhere. I am greatly indebted to Dr. E. Orowan for suggesting the possibility of using transparent, polycrystalline materials in the way described and for discussion of the results.

SCIENTIFIC RESEARCH AND INDUSTRY

SIR EDWARD APPLETON'S address to the Scottish Council (Development and Industry) at Glasgow on February 13 on "Science and the Progress of Industry" will increase the impatience with which the scientific and industrial world awaits the resumption of publication of the annual reports of the Department of Scientific and Industrial Research. Indeed, it could well be held that here again, as in the recent speech at Letchworth of the Lord President of the Council (see *Nature*, February 7, p. 214), by using a speech to a sectional or limited audience, which even in normal times could only be imperfectly reported in the Press, as the occasion for important announcements of policy or disclosure of developments, the Government is showing lack of courtesy to the scientific man and to the industrialist. Such statements should be put on permanent record in a proper fashion. Whatever may be the rights and wrongs of any policy—for example, the present dispute between the Government and the medical profession—it is to be hoped that the Government will learn that it is wiser to court than to flout the expert and professional experience upon the co-operation of which the smooth running of so many Departments of State depends. As Burke once remarked in another connexion, magnanimity in politics is not seldom the truest wisdom, and little minds go ill with a great State department or with a great Empire.

After a tribute to the work of Scottish men of science in the past, Sir Edward suggested that for an overall picture of the pattern of the scientific effort in Great Britain, it is useful to think of its three great sections—research in universities and technical colleges, Government research and research in industry itself—as being situated at the three corners of a triangle and thus linked directly together. He believes that the first task is to foster fundamental research in universities and technical colleges, where the really revolutionary industrial advances usually have their origin. Such fundamental research knows no national frontiers, but Sir Edward paid here a further tribute to the Scottish contribution, before referring more specifically to the essential contribution of the geologist to those problems of making the best use of familiar materials and of developing in the national interest materials so far regarded as economically useless. The Scottish Branch of the Geological Survey was always ready to help, but the problems of application involved belong to other branches of science. If the inquiries now being carried out by the Scottish Council revealed gaps in the facilities available for research, the Department of Scientific and Industrial Research would always be ready to consult with the Council as to how they could best be filled.

Before dealing with the work of the Department itself, Sir Edward indicated a few of the special grants made to workers in the Scottish universities; for example, to Prof. P. I. Dee in Glasgow and Prof. N. Feather in Edinburgh for work on nuclear physics, to Dr. C. Horrex at St. Andrews for work on the relative speeds of the decomposition of certain organic compounds, to Prof. G. D. Preston at Dundee for work on the development and use of the electron microscope, and to Prof. R. N. Arnold at Edinburgh for work on the cutting of metals at high speeds.

Emphasizing then the national character of the thirteen research stations of the Department, Sir Edward admitted that while, for example, the work which is being done in developing the science of building is equally applicable north and south of the Tweed, in considering the application of such science to particular problems, there may be considerable difference between the problems of the south of England and those of Scotland. For this reason, it has been decided to establish at East Kilbride branches of the Road Research Laboratory, the Building Research Station and the Fuel Research Station.

Sir Edward said that in co-operation with the County Surveyor of Lanarkshire and the Ministry of Transport, full-scale experimental surfacings are already under observation in that county. Two of these are duplicates of experiments on the Colnbrook Bypass near London, one being concerned with long-life asphalt and the other with tar- and bitumen carpets. The object of both these experiments is to ascertain how far conclusions, valid in the south of England, are also valid in Scotland, where the weather tends to be wetter and cooler. Another experiment in Lanarkshire is concerned with the use of wetting agents to improve the adhesion of bituminous binders to a local stone. The County Surveyor of Ayrshire is co-operating in experiments in the use of quarry waste in bituminous surfaces; the County Surveyor of Wigtownshire in the use of local sands, and the County Surveyor of Dumfriesshire in experiments on the use of chemicals for removing ice from roads.

Again, the Building Research Station has carried out work in conjunction with the Scottish Department of Agriculture on building materials composed of peat and cement, and investigations have been made into the suitability of clays from north-east Scotland for brick manufacture. There is already close association between the Fuel Research Station and the manufacturers and others interested in fuel problems in Scotland; but co-operation will be further strengthened by the establishment at East Kilbride of a sub-station of the Fuel Research Organisation. This sub-station will, in the first place, be occupied mainly in testing domestic heating appliances, but it will also serve as a liaison establishment in dealing with other local fuel problems and will ensure full appreciation at Greenwich of Scottish conditions and preferences.

The new laboratory for research into mechanical engineering science of the Department of Scientific and Industrial Research is also to be erected at East Kilbride. Sir Edward said that when, after the War, the Advisory Council for Scientific and Industrial Research came to review the research needs of Great Britain, certain gaps were evident in the facilities for research in this field. The most important of these were in hydraulic machinery, pumps and so forth, in heat transfer problems, in applied thermodynamics, and in kinetics and mechanisms. It will be part of the job of the new establishment to fill in these gaps; but its main task will be basic research in mechanical engineering science, which will have general application in due course throughout the whole of the industry. The work has been divided into groups which are, in fact, the underlying subjects of general application in many branches of mechanical engineering; in addition to those already mentioned, the properties of metals, problems of vibration, of lubrication, of noise, and of the mechanics of the formation and machine-shaping of metals are included.

Speaking of the research associations, Sir Edward made two interesting comments. Thirty-five industries now possess active research associations, some, such as the Iron and Steel, and the Electrical Research Associations with incomes of the order of £250,000 a year, and all with incomes permitting the prosecution of research on a substantial scale, possibly three or four times the pre-war scale. This increase in the scale of working, he suggested, largely disposes of the basis of previous criticism of co-operative research. Secondly, he referred to the use by certain associations, such as the Cotton, the Refractories and the Iron and Steel Research Associations, of the technique of what was called during the War 'operational research'. In industry this means obtaining a quantitative estimate of the dependence of the efficiency of industrial operations on various factors, and studies already made in some branches of industry have indicated immediate steps which could be taken to increase output by as much as twenty per cent. Statistical studies of a different kind made by the Boot and Shoe Research Association have shown that it is possible to increase the chance of being able to fit any customer and to reduce materially the number of sizes to be manufactured and stocked.

Of research by individual firms, Sir Edward remarked that the ultimate decision on how far new ideas springing from science are to be applied in industry rests with industry itself, and the manner of that application is a problem to be determined by the management. Nor is any generalization possible as to the necessity for, or type of, research department in an individual firm: there are industries which can safely rely on research carried out for them in outside organisations, provided they have the technical staff capable of interpreting the results of the work and applying and developing it to meet their particular requirements. No firm can afford to neglect such development, and Sir Edward insisted that Britain can only remain a great industrial nation if the industrial scene is kept under view and opportunities watched for applying science. This is work that the Scottish Council is well equipped to do for Scotland, and the office which the Department of Scientific and Industrial Research has established in Edinburgh is intended to assist the Council in such work. A main task of this new office is to assist the utilization of existing knowledge by putting the man with the problem into direct touch with the man who can solve it.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, March 8

INSTITUTE OF PETROLEUM, NORTHERN BRANCH (at the Engineers' Club, Albert Square, Manchester), at 6 p.m.—Mr. E. Thornton: "The Fighting of Oil Fires".

ROYAL INSTITUTE OF CHEMISTRY, LONDON AND SOUTH-EASTERN COUNTIES SECTION (at Woolwich Polytechnic, Woolwich, London, S.E.18), at 6.45 p.m.—Dr. H. Baines: "Colour Photography".

TEXTILE INSTITUTE (at 16 St. Mary's Parsonage, Manchester), at 7 p.m.—Dr. B. P. Ridge: "Some Aspects of Synthetic Fibres".

INSTITUTION OF THE RUBBER INDUSTRY, MIDLAND SECTION (at Burton-on-Trent), at 7.15 p.m.—Mr. L. E. Puddefoot: "Rubber Adhesives".

Tuesday, March 9

UNIVERSITY COLLEGE, LONDON (in the Anatomy Theatre, Gower Street, London, W.C.1), at 1.15 p.m.—Prof. H. E. M. Barlow: "Applications of Micro Waves".*

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 5 p.m.—Prof. W. E. Le Gros Clark, F.R.S.: "Recent Discoveries of Fossil Hominoids in Africa".

Zoological Society of London (at the Zoological Gardens, Regent's Park, London, N.W.8), at 5 p.m.—Scientific Papers.

Royal Institution (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Sir John E. Lennard-Jones, F.R.S.: "Modern Theories of Chemical Valency". (Further Lectures on March 16 and 23.)

Institute of Physics, Electronics Group (at 47 Belgrave Square, London, S.W.1), at 5.30 p.m.—Dr. H. A. Jahn: "Comparison of Atomic and Nuclear Energy Levels".

Institution of Chemical Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. W. H. Wheeler and Mr. J. E. C. Topps: "Rocket Propulsion, a Restricted Survey".

Institution of Civil Engineers (at Great George Street, London, S.W.1), at 5.30 p.m.—Prof. C. A. Hart and Mr. B. F. J. Bradbeer: "Air Survey and the Road Engineer".

Illuminating Engineering Society (at the Lighting Service Bureau, 2 Savoy Hill, London, W.C.2), at 6 p.m.—Mr. H. G. Jenkins and Mr. J. N. Bowtell: "High Voltage Fluorescent Tubes".

Manchester Geographical Society (at the Geographical Hall, St. Mary's Parsonage, Manchester), at 6.30 p.m.—Mr. John Coatman: "On Musa Ka Musalla".

Wednesday, March 10

Institute of Petroleum (at Manson House, 26 Portland Place, London, W.1), at 5.30 p.m.—Mr. H. S. Gibson: "The Production of Oil from the Fields of South-West Iran".

British Institution of Radio Engineers, North-Eastern Section (at Neville Hall, Westgate Road, Newcastle-upon-Tyne), at 6 p.m.—Mr. I. A. Harris: "The Calculation of Electrode Temperatures in the Radio Valve".

Society of Chemical Industry, Microbiological Panel of the Food Group (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.15 p.m.—Annual General Meeting; at 6.30 p.m.—Papers on "The Microbiological Control of Therapeutic Products".

Institution of the Rubber Industry, Southern Section (at the Polygon Hotel, Southampton), at 7.15 p.m.—Mr. A. E. Moulton: "Rubber in Railway Operation".

Institute of Welding, North London Branch (at the Technical College, Acton, London, W.3)—Mr. E. Ryalls: "The Bronze Welding of Cast Iron".

Thursday, March 11

East Malling Research Station (at Bradbourne, East Malling Research Station, East Malling, Kent), at 4 p.m.—Capt. R. Wellington: "Fruit Research—some Thoughts Past and Future".*

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. D. W. E. Axford and Prof. R. G. W. Norrish, F.R.S.: "Oxidation of Gaseous Formaldehyde"; Sir Alfred Egerton, F.R.S., and Mr. J. Powling: "The Limits of Flame Propagation at Atmospheric Pressure", Parts 1–2.

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—"Survey of the Outer Hebrides". (Dr. James W. Campbell: "Birdlife"; Miss M. S. Campbell: "Plant Collecting".)

Physical Society, Acoustics Group (joint meeting with the British Sound Recording Association, at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 5.45 p.m.—Discussion on "Loudspeakers, with Particular Reference to High-Fidelity Monitoring Reproducers" (to be opened by Dr. D. E. L. Shorter).

Anglo-Austrian Society (at the British Council, 6 Hanover Street, London, W.1), at 6.30 p.m.—Prof. J. R. Marrack: "The World Food Situation".*

Chemical Society (in the Chemistry Department, The University, Manchester), at 6.30 p.m.—Prof. H. L. Riley: "Amorphous Carbon".

Society of Chemical Industry, Food Group (joint meeting with the Nottingham Section of the S.C.I., at the Welbeck Hotel, Nottingham), at 7.15 p.m.—Mr. W. Cunliffe: "Physical Chemistry of Food with particular reference to Bakery Products".

Chemical Society, Society of Chemical Industry, and Royal Institute of Chemistry, Edinburgh and East of Scotland Sections (at the North British Station Hotel, Edinburgh), at 7.30 p.m.—Dr. E. S. Paice: "Practical Aspects of Wetting and Detergency".

Pharmaceutical Society (at 17 Bloomsbury Square, London, W.C.1), at 7.30 p.m.—Sir Weldon Dalrymple-Champneys, Bart.: "The Work of the Medical Staff of the Ministry of Health".

Pharmaceutical Society, Manchester, Salford and District Branch (in the Council Chamber, Houldsworth Hall, Manchester), at 7.45 p.m.—Papers on "The New British Pharmacopœia".

British Institution of Radio Engineers, North-Western Section (in the Reynolds Hall, College of Technology, Sackville Street, Manchester).—Mr. M. P. Johnson: "Some Aspects of Moderate Precision Temperature Control in Communication Engineering".

Friday, March 12

Biochemical Society (in the Department of Biochemistry, University College, Gower Street, London, W.C.1), at 2 p.m.—Annual General Meeting; Scientific Papers.

Oil and Colour Chemists' Association, Manchester Section (at the Engineers' Club, Albert Square, Manchester), at 2 p.m.—Mr. H. V. Clay and Mr. V. Watson: "Physico-chemical Studies of Lead Chromes".

Physical Society (in the Physics Department, Imperial College of Science, Imperial Institute Road, London, S.W.7), at 5 p.m.—Scientific Papers.

Institute of Navigation (at the Royal United Services Institution, Whitehall, London, S.W.1), at 5.30 p.m.—Mr. P. F. Everitt: "Air Sextants"

British Association of Chemists, Birmingham Section (at the University, Edmund Street, Birmingham), at 6.30 p.m.—Prof. W. Wardlaw: "Valency".

Institute of Physics, Manchester and District Branch (in the New Physics Theatre, The University, Manchester), at 7 p.m.—Prof. P. A. Sheppard: "The Physics of Meteorology".

Sheffield Metallurgical Association, Methods of Analysis Group (at 198 West Street, Sheffield), at 7 p.m.—Mr. H. Groom: "Absorptiometric Determination of Manganese".

Chemical Society (in the Chemistry Lecture Theatre, The University, Glasgow), at 7.15 p.m.—Prof. E. L. Hirst, F.R.S.: "Some Problems in the Chemistry of Starch and Glycogen".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. T. E. Allibone: "Lightning and Spark Phenomena".

Saturday, March 13

Nutrition Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 10 a.m.—Conference on "Results of Recent Investigations into Nutritional Status in Great Britain".

British Psychological Society (in the Physiology Theatre, University College, Gower Street, London, W.C.1), at 2.30 p.m.—Mr. J. C. Raven: "The Comparative Assessment of Intellectual Ability".

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Dr. M. Fortes: "The Cocoa-Farmers of the Gold Coast".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Chemist in the India Store Department—The Director-General, India Store Department, Blackpool, quoting S.4527/47 (March 8).

Area Supervisors or Assistant Area Supervisors, and a Laboratory Steward, in the West Midland Province—The Provincial Supervisor, National Milk Testing Service, Ministry of Agriculture and Fisheries, Bank House, Newport, Shropshire (March 12).

Lecturer in Agriculture and Farm Bookkeeping, and a Lecturer in Agriculture, Farm Implements, Building Construction, etc., at the Cheshire School of Agriculture, Reaseheath—The Director of Education, County Education Offices, City Road, Chester (March 13).

Agricultural Adviser for the County of Angus—The Secretary, Edinburgh and East of Scotland College of Agriculture, 13 George Square, Edinburgh 8 (March 15).

Assistant Lecturer in Theoretical Physics—The Registrar, The University, Manchester 13 (April 17).

Chief Mining Engineer, Salt Range Division, Khewra, West Punjab—The High Commissioner for Pakistan, 16 Fitzhardinge Street, London, W.1 (March 19).

Physical-Chemist to work on chemical reactions in emulsion systems, a Physicist or Physical-Chemist to work on properties of plastic-elastic materials, and a Chemist with experience of abstracting, etc.—The Secretary, Research Association of British Rubber Manufacturers, 105 Lansdowne Road, Croydon, Surrey (March 27).

Forecasters in the Meteorological Branch, Air Department, New Zealand—The Office of the High Commissioner for New Zealand, 415 Strand, London, W.C.2 (March 31).

Robert Blair Fellowships in Applied Science and Technology—The Education Officer (H.1/2), London County Council, County Hall, London, S.E.1 (April 1).

Senior Principal Scientific Officer in the Royal Naval Scientific Service—The Secretary, Civil Service Commission, Scientific Branch, 27 Grosvenor Square, London, W.1, quoting No. 2123 (April 7).

Assistant Editor—The General Secretary, Chemical Society, Burlington House, Piccadilly, London, W.1 (April 12).

Ramsay Memorial Fellowships for Chemical Research—The Joint Honorary Secretaries, Ramsay Memorial Fellowships Trust, University College, Gower Street, London, W.C.1 (April 17).

Head of the Department of Surveying and Engineering—The Principal, College of Estate Management, 11 Great George Street, London, S.W.1 (May 1).

Assistant Lecturer (Grade III) in the Department of Biochemistry—The Registrar, The University, Liverpool (May 1).

Dental Research Fellow—The Dean, Medical School, Guy's Hospital, London, S.E.1 (May 31).

Professor of Civil Engineering in the University of Queensland, Brisbane—The Agent-General for Queensland, 409 Strand, London, W.C.2, and The Secretary, Universities Bureau of the British Empire, 8 Park Street, London, W.1 (Brisbane, May 31).

Head of the National College for Heating, Ventilating, Refrigeration and Fan Engineering—The Clerk to the Governors, Borough Polytechnic, Borough Road, London, S.E.1.

Laboratory Technicians with experience in cutting and staining sections—The Dean's Office, St. Thomas's Hospital Medical School, London, S.E.1.

Research Assistants (with Inter.B.Sc.) for work in Organic Chemistry section, in Leatherhead—The Assistant Secretary, British Coal Utilization Research Association, 13 Grosvenor Gardens, London, S.W.1.

Demonstrator in the Division of Chemistry—The Bursar, Royal Veterinary College and Hospital, Royal College Street, London, N.W.1.

Biochemist (male, with B.Sc. chemistry) in charge of routine hospital biochemical laboratory—The Secretary, Ministry of Health Laboratory, Peace Memorial Hospital, Watford.

Demonstrator in the Physiology Department—The Warden and Secretary, Royal Free Hospital School of Medicine, 8 Hunter Street, London, W.C.1.

Technicians (2, Grade B)—The Medical Director, Coventry Joint Laboratory, Stoney Stanton Road, Coventry.

COLONIAL DEVELOPMENT AND INTERNATIONAL CO-OPERATION

THE increasing tempo of development in Colonial territories, and also the urgent need for integrating their economy with that of Europe as a whole, have given added importance to published studies of Colonial administration. A recent one[*], by Mr. Martin Wight, is the first study made of a Colonial legislative council in action, and has political as well as constitutional significance. Mr. Wight attempts to put the legislative council in its place against the life and society of one of the most progressive British dependencies in Africa. Beginning with a factual study of the history and practice of the legislative council over the twenty years from 1925, it affords a valuable introduction to the appraisal of the new constitution of 1946 in which the legislative council became the legislature for Ashanti as well as for the Gold Coast Colony, and was at the same time transformed into a representative legislature in which the official majority has been replaced by an unofficial, elected, African majority.

Mr. Wight comments on the significance of this first introduction of representative government into Africa outside the colonies of white settlement, in the general context of British Colonial government. His book well indicates how this step is in keeping with the spirit that has inspired British Colonial government since Sir James Stephen's days, and should do something to convince Africans that we share with them both the ultimate vision and something of the ardour and urgency which they are bringing to its realization. In seizing on the legislative council, which has long been the growing point of constitutional development in the Colonies, for the starting point of this series, the Colonial Research Committee appointed by Nuffield College could scarcely have demonstrated better the capacity of such research on contemporary political and economic questions to contribute to an understanding of these problems by both the white and the coloured peoples, and to the effective collaboration which is required for their solution.

A second reason for welcoming this survey of Colonial administration is the value of such a conspectus in relation to the latest approach to international co-operation in this field. The survey has its place in rebutting the uninformed criticism which has sometimes come into discussions related to the trusteeship proposals in the United Nations Organisation; but it is even more pertinent in regard to such developments as those on which the Foreign Secretary just touched in his speech in the House of Commons on January 22. Pointing out that the organisation of Western Europe requires economic support, he emphasized that such support involves the closest possible collaboration between the British Commonwealth and overseas territories, French, Dutch, Belgian and Portuguese as well as British. These overseas territories are large primary producers, with a standard of life which is rising and is capable of great development. They have raw materials, food and resources which can be turned to very great common advantage, and Mr. Bevin suggested that to enable Western Europe to achieve its balance of payments and a world equilibrium, it is essential that those resources should be made available and the exchange between them carried out correctly.

---

[*] The Gold Coast Legislative Council. By Martin Wight. (Studies in Colonial Legislatures, Vol. 2: Published under the auspices of Nuffield College.) Pp. 285. (London: Faber and Faber, Ltd., 1947.) 12s. 6d. net.

Mr. Bevin did not pursue this idea into any detail. He affirmed that there is no conflict between the social and economic development of these overseas territories to the advantage of their people, and their development as a source of supplies for Western Europe as a contributor to the balance of payments. He merely indicated the Government's intention, if the Marshall Plan for American aid to Europe is accepted, to develop economic co-operation between Western European countries step by step, to develop the resources of the territories with which we are associated, and to build up a system of priorities which will yield the quickest, most effective and most lasting results for the whole world; it is also hoped that other countries with dependent territories will do the same in association with us.

Mr. Bevin's vision of the tremendous resources stretching through Europe, the Middle East and Africa, to the Far East, being brought together with the object of making the whole world richer and safer, involves economic and social planning on a bolder and more imaginative scale than the world has yet seen. None the less, the opportunity may well be there, and although this imaginative passage in his speech has largely escaped notice, there is already evidence that the European Powers concerned in Colonial administration are drawing closer together. The Royal Institute of International Affairs has recently published* a series of papers on Colonial administration read at King's College, London, in November and December 1946. Contributions from French, Dutch, Belgian and Portuguese administrators, side by side with Lord Hailey's review of British Colonial policy, are brought together, not merely to exchange experience and compare methods, but also to lay down general principles which may assist in the re-orientation of both policy and practice to meet the latest developments and the accelerated urge towards independence in the Colonial territories.

M. le Gouveneur H. Laurentie, in his review of recent developments in French Colonial policy, notes that in spite of frequent differences in method, Great Britain and France, inspired by their common belief in the freedom, the dignity and the reason of man, have set themselves the same goal. Dr. A. M. Joekes likewise concludes a very clear and pertinent exposition of developments in the administration of Indonesia with the hope that the assistance given by Britain in clearing up the situation in Indonesia will be a corner-stone for close and fertile co-operation between Great Britain and the Netherlands in protecting and promoting the well-being of both countries, and Dr. R. Godding's review of principles and methods now being followed in the Belgian Congo is of profound interest for such projects as the East African groundnut scheme. Scientific workers will note with special interest the reference to the National Institute for Agricultural Research in the Belgian Congo, and the emphasis laid on research. The twenty-one research and experimental stations now scattered all over that Colony, covering the various climates, soils and altitudes, have, in fact, something in common with the idea of pilot schemes developed by Dr. E. B. Worthington in his plan for Uganda.

One argument submitted by Dr. Godding in favour of the Belgian method of development is that cultivation of large modern plantations on scientific lines with up-to-date machinery affords much higher yields of produce of better quality, and in consequence a much larger return, to be ploughed back, as it were, in the form of educational, social, medical and material improvements in the native standards of living. Dr. Godding also referred to the formation of an institute of scientific research in the Congo, which would cover such fields as geology, botany, meteorology, sociology and medicine. It was intended to endow this institute with large resources, and it was hoped that it would become a kind of international research station for tropical Africa.

Such developments clearly provide substantial backing for the vigorous defence of Western democratic administration with which Dr. Godding concludes, and he too referred to the inspiration which the Western democracies draw from humanism and Christianity in this task, which, he affirmed, they would perform in a spirit of human solidarity with the coloured races. Dr. José de Almada similarly concluded his survey of Portuguese Colonial administration with the comment that the modern world leaves no room for privilege, economic domination or social injustice, any more than it can tolerate ignorance, disease, malnutrition and extreme poverty.

Lord Hailey's survey was more severely practical, emphasizing first the influences which had gone to form the modern British outlook on the general direction of Colonial policy and the measures taken to give it effect. Here he pointed out that in widening the franchise for the legislatures and extending their legislative powers, we should satisfy ourselves that such institutions are developing so as to secure the interests and confidence of the mass of the people; for this is the real measure of their success. Similarly, in admitting the native peoples to the State services and such administrative institutions as executive councils, there is the difficulty and danger of accepting those of doubtful competence or character. Again, Lord Hailey emphasized that for all the educative influence of the method of indirect rule it has its limitations, and we have not yet succeeded in making it popular with the more educated community or with the middle class or commercial elements.

---

* Colonial Administration by European Powers: a Series of Papers read at King's College, London, 14 November to 12 December 1946. By José de Almada, Robert Godding, Lord Hailey, A. M. Joekes and H. Laurentie. Pp. xiii+97. (London and New York: Royal Institute of International Affairs, 1947.) 4s. 6d. net.

These are matters to which due attention will doubtless be given at the conference of unofficial members of the African Legislative Councils which is to be held in London later this year. Two things, however, stand out very clearly from this series of papers: first, the general disposition to examine anew the principles which have shaped the Colonial systems of the Western democracies, and to test the adequacy of the existing structure to meet the demands which the future seems likely to make upon it; and, secondly, the large measure of implicit support in the Colonial territories for the ideas of Colonial co-operation which Mr. Bevin ventilated in the most imaginative passage of his recent speech. The chapter on international relations in the Blue Book on "The Colonial Empire, 1939–1947" (Cmd. 7167) indicates how much has already been done to prepare the way, particularly in co-operation with the French and Belgian Governments. In his speech in the House of Commons on July 29, Mr. Creech Jones particularly stressed the three years programme of conferences in technical matters between these three Governments in Africa which had already been agreed, and his words are strikingly similar to those of Mr. Bevin in regard to the larger issue of Colonial development and European needs.

Scarcely less significant, however, is the emphasis placed by Mr. Creech Jones in this speech, in the Blue Book, and also in the papers just noted, on the importance of the contribution which the scientific worker himself must make in such developments. References to research in the Blue Book and also in Mr. Creech Jones' speech show how ready should be the response of the British Government to the lead which, as Dr. Godding showed, the Belgian Government has given in certain fields. Problems of Colonial welfare and development, in their scientific aspect, were considered by several sections of the British Association at its meeting in Dundee last year, while elsewhere current discussions on game slaughter in Africa in connexion with the control of tsetse fly and trypanosomiasis have emphasized the need for proper research, to which adequate finance is the key, in yet another field, and in particular the linking of research with authoritative administrative co-operation.

There are, indeed, many reasons why scientific men should take an increasing interest in Colonial affairs generally. For the solution of a wide range of Colonial problems their co-operation is essential, and frequently those same problems are linked to scientific problems of fundamental importance. Further, as citizens, they cannot be indifferent to the wider implications, in the material and economic field, and in the greater task of building those Colonial and international institutions which may best serve the highest cultural and moral needs of men. In seeking thus to provide the means of safeguarding both human welfare in its physical and material sense, and the great heritage of freedom and creative achievement which Western civilization has given to the world, we shall simultaneously further the nurture and advance of science itself.

EARLY ENGLISH NATURALISTS

English Naturalists from Neckam to Ray

A Study of the Making of the Modern World. By the Rev. Charles E. Raven. Pp. x+379. (Cambridge: At the University Press, 1947.) 30*s*. net.

Dr. C. E. Raven has followed up his remarkable work on John Ray by another, equally learned, on the early English naturalists. His purpose in the latter "began as a series of biographies. But very soon it became clear that the succession of 'lives' not only formed a very definite pattern, but that this illustrated and illuminated the progressive change in Western civilization from the medieval to the modern world." Again, "in Man's attitude to living nature the process of a gradual overcoming of superstition and fabulous tradition, and the development of the modern scientific spirit as a result, is significant and may be followed from man to man. . . . Little by little nonsense was recognized, fables were exploded, superstitions were unmasked; and the world outlook built up out of these elements fell to pieces." The thesis is not a new one, nor is it one that admits of serious dispute, but Dr. Raven has brought to bear upon it a wealth of new matter, the result of prolonged and detailed critical research. These notable additions to our knowledge have been exhumed often from little-known and unpromising sources, and they enrich and distinguish the author's bio-biographies of such naturalists as William Turner, John Caius, Thomas Penny, Thomas Mouffet, John Gerard, Edward Topsell, John Parkinson and Thomas Johnson. Dr. Raven's method, however, has one drawback. It complicates what is known as documentation, and a text frequently halted by the intercalation of bibliographical detail is apt to be tedious to follow. It is better to preserve the flow of the narrative even if it involves some sacrifice of meticulosity. In a future edition we hope to see the author's sources collected and printed in alphabetical order at the end of the text. But however this may be, historians of biology must welcome so scholarly an addition to their studies and literature.

The history and emergence of the modern outlook on science has been to many workers an attractive and fruitful field of research. The preceding or medieval period, based as it was on scholasticism, symbolism and the ingenuous acceptance of attractive but flagrant fables, was not only incapable of producing an integrated body of science, but would have been even hostile to it. As Dr. Raven remarks, the contest between an untenable tradition and the induction of the men who loved and lived by the world of plants and animals unhappily resulted in giving "for a time to the ancient writings an authority, indeed an infallibility, very damaging to progress. So long as Aristotle and Galen, or for that matter Genesis and the Apocalypse, were accepted and imposed as inerrant, it was difficult to encourage the investigation of the facts with which any real advance must begin. This delayed, though it could not prevent, the coming of the new outlook." Such is Dr. Raven's theme, and his scrutiny of the works of the early naturalists provides us with a convincing and orderly exposition of it. His most successful biography is that of William Turner, but much new light is thrown upon the works of Penny, Mouffet, Parkinson and Merrett. The book learning of Wotton, the author of a beautifully printed zoological treatise dated 1552, is rescued from undeserved obscurity, but Gerard's "Herbal" is severely, if justly, handled. Dr.

Raven, however, gives us an admirable analysis of the second edition of this famous book which had been competently revised and amended by Thomas Johnson. There are some omissions, such as Thomas Hill and Charles Butler—the latter one misses particularly, since he represents a type that Dr. Raven delights to reanimate.

Here are a few minor addenda and corrigenda. P. 58: Gaza's Latin translations of the biological works of Aristotle and Theophrastus were first printed at Venice, 1476, and Treviso, 1483. P. 145: Caius' "maculo" was evidently one of the Serranid fishes, some of which attain a length of 10 ft. The length given, 60 ft., is clearly an error, possibly for 6 ft. Caius' "ceruchus" could not be a sturgeon, but was undoubtedly the angler *Lophius*, as first pointed out by Jonathan Couch in 1862. The name is derived from the Greek and refers to the horn-like lures of the fish. Belon's "true picture of the dolphin" was first published in 1551 and only later in the "De Aquatilibus" of 1553. Hence Caius was not necessarily acquainted with the latter work. P. 180: Mouffet's unpublished engraved title-page was first described and reproduced by Mullens in 1911. P. 188: A comparison of Mouffet's woodcuts with the drawings of the original MS. is necessary in assessing the accuracy of the author. P. 220: The Su, which receives only a bare mention, is one of the most remarkable figures in Topsell, and he copied it from Gesner, who in his turn took it from Thevet of 1558. The description of this animal fits in with no known species, but it cannot be doubted that the figure was inspired by the sight of an American opossum carrying its young on its back. P. 221: The history of Dürer's rhinoceros in zoological literature is curiously relevant to the soundness of Dr. Raven's theme. P. 230: The commonly accepted biographical details relating to Leonard Mascall were shown to be inaccurate by Sir Frederick Smith in 1919. Nothing certain is known of Mascall's career. P. 235 *passim* and index: Jan Jonston's name is wrongly spelt. P. 337: The inexact quotation from Sir Thomas Browne is apparently taken from Wilkin, who was not always an accurate transcriber of Browne's manuscript, and "Turn" was understood to be Turner by Southwell in 1902. F. J. COLE

MEN OF SCIENCE IN INDUSTRY AND SOCIETY

The Engineer in Society

By John Mills. Pp. xix+196. (New York: D. Van Nostrand Co., Inc.; London: Macmillan and Co., Ltd., 1946.) 14*s*. net.

THE right relation of knowledge and power—the means by which we can best secure that action in political and social no less than in industrial problems is determined after full regard to the scientific and technical factors as well as to the other elements in a situation—remains one of the central problems of our time. There are signs that appreciation of the importance of this problem has led to new attempts to find a solution. These attempts have clearly been on three lines: the provision of more effective administrative organisation by which the scientific worker can make his contribution; improvement of the training of the administrator; and the improvement of the training of the scientific man; while it has not been altogether overlooked that in a democracy the education of the ordinary citizen himself is also an important factor.

Mr. Mills in this book addresses himself squarely to the question why the scientific man, and more especially the engineer, does not occupy in society the position which his technical achievements and the part they have played in the radical transformation of the conditions of living would seem to warrant. He seeks to lay bare the reasons for his failure to do so, and to indicate by what steps he can take a more effective place in the control of the forces which his discoveries and inventions have released. But once again we find the physician surer at diagnosis than at prescription, and while there is much sound advice to the young industrial scientific worker, albeit frequently couched in jargon, or at least rather uncouth writing, Mr. Mills' contribution to the fundamental problem of how the man of science is to take a more effective place in the life of society is slight indeed. In that Mr. Mills concludes with half a dozen chapters on exposition in which the first essential to persuasive writing—clear thinking—is well brought out, and one chapter on "Reader Consciousness" indicates that Mr. Mills, at least in theory, is alive to the importance in either spoken or written exposition of considering first the needs and limitations of the audience or reader, he is at least open to the indictment that his practice is rather short of the standards he holds out for attainment.

What Mr. Mills has really given us in this book is something in the lineage of Samuel Smiles and "Sanford and Merton". It is a cautionary book for the scientific man or engineer contemplating or embarking on an industrial career. It abounds in suggestions, but few are pursued to any length; and indeed it is so discursive that adequate treatment of the themes raised would have made the book intolerably long, even had many of the irrelevancies been rigorously pruned. The author has something to say about the qualities which should determine the choice of research appointments as well as about the selection of men for the research—and the social waste when scientific talent of conspicuous ability is drawn off into administrative positions as soon as its full powers in research have been developed. On motives, incentives and salaries he is refreshingly forthright, sometimes provocative but usually stimulating, as further exemplified in some remarks on creative thinking in a chapter "The Art of Thought".

Mr. Mills comes nearest to his title theme in writing of professional associations, and his comments on the characteristic weaknesses of such bodies are just as pertinent to British organisations as to their American opposites. Nevertheless, he believes that scientific workers in industry should organise for their own protection and advancement, but even more for the great opportunities of social service which such organisation makes possible. In urging this he points out that this does not mean that scientific workers should be organised: his comment elsewhere on the tendency in present industrial conditions for the creative scientific man to lose his professional attitude deserves to be pondered when we are reviewing our whole organisation for scientific and industrial research. The problem which such professional bodies should examine is an engineering study of their class relationship to society. Commencing with a study of remuneration and of other incentives, he suggests that such a study might lead to others which will bring the engineer and scientific man into fruitful contact with the major problems of our time. If the project is attacked objectively by the scientific method, it should lead to results of social importance; and the core of the book really lies in Mr. Mills' plea for all scientific men of good will to join in an intelligent attack upon the social, economic and political problems of the day by an evolutionary application of the methods of science. Primarily that means a study of the problems of organisation, for the scientific method is to-day so little employed outside physical problems and, as Mr. Mills shows, is so diametrically opposed to the interests of particular classes, that its use in open attack may be impracticable. None the less, he believes its use is the last hope of our civilization, and his dignified plea for the engineer and scientific man to apply the objective method of science to the things directly affecting their lives and national surroundings without regard to inbred or subjective attitudes goes far to redeem his blemishes of style.

WIRELESS DIRECTION FINDING

Wireless Direction Finding

By R. Keen. Fourth edition. Pp. xii+1059. (London: Iliffe and Sons, Ltd., 1947.) 45*s*. net.

THE appearance of the fourth edition of this book will do much to dispel the impression, prevalent in some quarters, that the technique of radio direction finding has been rendered obsolete by the introduction and development of radar in recent years. As the author explains in his introductory chapter, there are several fields in which direction finding will still have commitments for many years to come. The relative simplicity of the equipment required to give guidance to ships and aircraft, and particularly to those in distress, makes it an invaluable aid to navigation; in another field, the network of direction finders provides the only means so far available of locating radio transmitting stations, and such information is frequently required under peacetime conditions as well as in time of war.

In spite of the fact that the present book excludes a discussion of radar technique as such, it is a considerable enlargement on the previous edition, which was reprinted four times during the War. The only new chapter added describes the recently developed radio navigation systems such as 'Gee', 'Loran', 'Decca' and 'Consol', some of which use pulse modulation and some continuous-wave technique. The remaining chapters have been suitably expanded to include material descriptive of advances and developments; much of this material has only recently become available for publication.

Two of the most important additions are the sections on the calibration of direction-finding systems of various types, and on the classification of observed bearings. On both these subjects there has been much confused thinking in the past, and their detailed study has resulted in considerable improvement in the accuracy with which radio bearings can be observed and interpreted. The subject of radio wave propagation at both high and very high frequencies is treated somewhat more fully, since a detailed knowledge of this is fundamental to the successful exploitation of direction finding.

The book has been brought up to date also by the addition of details of new equipment developed both in Great Britain and in the United States, and including blind approach and landing systems for aircraft, improved forms of the Adcock and spaced-loop aerial systems, and various types of cathode-ray tube presentation devices. The bibliography is, as in previous editions, an important feature of this book. With more than four hundred references, it forms a very useful guide to the literature of the subject, and it includes the titles of some papers still in course of publication.

As a comprehensive, practical manual on the various aspects of radio direction finding, the book can still be confidently recommended to students, engineers and other workers in this field.

NEWTON TERCENTENARY CELEBRATIONS

Royal Society

Newton Tercentenary Celebrations, 15–19 July 1946. Pp. xv+92+6 plates. (Cambridge: At the University Press, 1947.) 10*s*. 6*d*. net.

THE tercentenary of the birth of Sir Isaac Newton occurred in 1943. The Royal Society arranged at that time a commemorative meeting, and it was decided that more complete celebrations of an international character should be held after the War. These celebrations were held in July 1946, and invitations to send delegates were extended to the national academies of the world; in spite of the difficulties of travel, more than thirty countries were represented.

During the course of the commemorations, a number of addresses on various aspects of Newton's life and work were given, which were of considerable interest. These are all printed in the present volume, together with the list of delegates and the programme of the celebrations. It is well that they should be published in this way and so made available to a larger audience. The principal address, on "Newton", by Prof. E. N. da C. Andrade, gave a brilliant account of the life and achievements of Newton; in a very effective manner he called on the great men of science, from Newton's to the present time, to pay their tributes to Newton's genius. Among the other addresses of special interest were those on "Newton and the Atomic Theory" by Academician Vavilov; on "Newton: the Algebraist and Geometer", by Prof. H. W. Turnbull; and on "Newton, the Man", by the late Lord Keynes, which was read by his brother, Mr. Geoffrey Keynes.

At the opening address to the delegates, the president of the Royal Society announced that the Chancellor of the Exchequer had agreed to ask Parliament to vote a sum of money sufficient to provide an Isaac Newton Observatory, to house a reflector of 100-in. diameter, as a fitting national memorial to commemorate the tercentenary of the birth of the greatest British man of science. The design of this telescope is now under consideration by a special board of management which has been constituted.

The volume is illustrated with three portraits of Newton, an old engraving showing Newton's rooms at Trinity College, Cambridge, a drawing of Woolsthorpe Manor by Mr. Hanslip Fletcher, and a reproduction of a letter from Newton to Halley.

Plato's Theory of Education

By Prof. R. C. Lodge. With an Appendix on The Education of Women According to Plato, by Rabbi Solomon Frank. (International Library of Sociology and Social Reconstruction.) Pp. viii+322. (London: Kegan Paul and Co., Ltd., 1947.) 18*s.* net.

THE aim of this important book, by Prof. R. C. Lodge, of the University of Manitoba, is to meet the needs of students of educational theory, "of those who are interested in Plato as thinker and who find in him a standing challenge to their own powers of thought, and of that wider group who are seeking to enlarge their own vision". The author considers Plato as writer, teacher, and thinker who believed that in the balanced philosophic life is to be found the solution of all human problems. Prof. Lodge fulfils his promise in twelve admirably written chapters. Turn where you will in these chapters, and you are struck by their freshness, clearness and vitality. He writes as a scholar, but not for scholars only.

As to the bibliography, a British reader naturally expects to find certain names, and he does find the names of Nettleship and A. E. Taylor. But he wonders why no mention is made of Bernard Bosanquet, the distinguished author of "A Companion to Plato's Republic" and of "The Education of the Young in the Republic of Plato", published in 1900. There was good reason for omitting R. H. S. Crossman's "Plato Today" (1937), which is too exclusively British in its outlook to attract an American writer. Some of the British books mentioned by Prof. Lodge, though important in their own way, contain only bare references to Plato. For this there may be good reasons; but their inclusion looks rather odd.

Mechanics

By Prof. John C. Slater and Prof. Nathaniel H. Frank. (International Series in Pure and Applied Physics.) Pp. xiii + 297. (New York and London: McGraw-Hill Book Co., Inc., 1947.) 20*s.*

THE word 'mechanics', although derived from μηχανη, a machine or contrivance, is often used to describe the general treatment of natural philosophy by mathematical methods, and it is in this sense that the authors here employ it. This particular work is the first of several, which are intended to replace their "Introduction to Theoretical Physics", published in 1933, and is presumably to be followed by others on electromagnetism and quantum theory. In this dissection, it is believed that a better treatment of each field can be provided, at the same time preserving the general unity essential both to teacher and student.

The main emphasis here is on dynamics and the theory of vibrations, and the first seven chapters are devoted to the classical development of this theory. After the enunciation of Newton's laws of motion the fundamental principles of particle and rigid dynamics are deduced, to be followed by the methods of Euler, Lagrange and, finally, Hamilton. Special vibration problems are then considered, such as those of a string, a membrane, and an elastic solid, and the last chapter is concerned with the elements of irrotational fluid flow. A number of appendixes are also provided to elucidate the properties of complex numbers, vectors, tensors, Fourier series and Bessel functions, which have been previously utilized in the main text.

The whole work is beautifully bound and clearly printed on good quality paper, and should prove a useful book of reference. J. H. PEARCE

Die Bluteiweisskörper des Menschen

Untersuchungsmethoden und deren klinisch-praktische Bedeutung. Von Dr. F. Wuhrmann und Dr. Ch. Wunderly. Pp. 354. (Basel: Benno Schwabe und Co., 1947.) 36 Swiss francs.

THIS book is divided into three parts, of which the first deals with the general physico-chemical properties of serum proteins. The second chapter considers methods used in the study of serum proteins: electrophoresis, ultracentrifugation, colour tests such as the Millon reaction, and finally a series of empirical clinical methods such as the Takata reaction, among them some not in use in Britain. In the third part an account is given of the changes occurring in diseases as revealed by the methods described previously. The fourth chapter groups diseases according to the serum fraction mainly affected by them. The concluding chapters sketch the formation of blood proteins (13 pages) and the therapeutic application of serum fractions (17 pages).

A work such as this, written by five authors, will necessarily show some unevenness; but by more severe editing, some repetitions might have been prevented. In the pathological sections, English literature is not sufficiently taken into account. In the chapter on nephrosis, for example (p. 281), out of fifty references, only one is to an American publication, and there is not one to a British journal. In spite of these shortcomings, the book contains much valuable information and will enable workers in this field to get an insight into the trends of research in Switzerland.

Recent Advances in Endocrinology

By Prof. A. T. Cameron. Sixth edition. Pp. vii+443. (London: J. and A. Churchill, Ltd., 1947.) 21*s.*

IN form, this sixth edition does not differ from its predecessor, which was published in 1945, and the revisions it incorporates are in general only slight. The more important additions are paragraphs on the treatment of hyperthyroidism with thiouracil, and on the iodoproteins; further information about the effects of adrenalectomy and the treatment of Addison's disease; and some interesting new facts about the parathyroids. The book is a very useful summary of the whole field of hormone studies, and it is bound to enjoy the success of previous editions.

Exploring Our National Parks and Monuments

By Devereux Butcher. (Published under the auspices of the National Parks Association.) Pp. 160. (New York and London: Oxford University Press, 1947.) 15*s.* net.

THE United States have long given a lead to the world in the matter of national parks. Although the Yellowstone Park is world-famous, it is but one of their many Nature reserves, embracing some twelve million acres of land, lake and forest. There are reserves from Maine to California and from Alaska to Florida. This book by the executive secretary and editor of the National Parks Association of America is a guide to their twenty-four national parks and thirty-eight Nature monuments. It gives a description of each reserve, its scenery and fauna; also how to reach it and the accommodation available for visitors. The many photographic illustrations are excellent and more than tantalizing for the English reader, whose travel opportunities are now so restricted. The book is well produced and admirably fulfils its object. FRANCES PITT

OPERATIONAL RESEARCH

By SIR CHARLES GOODEVE, O.B.E., F.R.S.

DEFINITION AND USE IN WAR

THE term 'operational research' came into prominence during the War to describe what to the Services was a new type of thinking process used to arrive at answers to questions arising out of the operations of war. This thinking process has, however, already to some extent been used in industry under other names. It has been applied to market problems, cost accounting, quality control and works efficiency; in other words, to the operations of industry[1]. It has also been applied to agriculture and medicine. Its successful application during the War is already stimulating and extending its peace-time application.

Operational research has been defined in various ways. I commonly call it "quantitative commonsense"; but more specifically, *operational research is a scientific method of providing executive departments with a quantitative basis for decisions regarding the operations under their control.* This definition is based on that put forward by Kittel[2] and is preferable to the more complicated and limited one put forward by Watson-Watt[3]. According to the scientific method reliance is placed only on controlled experiments or on experiences, the observations of which can be analysed. From the analysis, conclusions are deduced, using the rigorous logic of mathematics and statistics.

The applied nature of operational research is shown by its association with executive decisions, and it follows that workers in this field must be closely in touch with, if not part of, executive departments.

The field of operational research depends on the interpretation of the word 'operations' in the definition. This paper attempts such an interpretation by means of illustrations. In war, operational research was applied to the use of weapons, to tactics, and to strategy. In the peace-time application of operational research, studies are directed, for example, to the use of equipment and man-power, to operating procedures, and to the solution of those many problems faced by management in operating or controlling factories or public utilities, or by Government authorities in planning. The field of operational research is very wide; but it will be seen that it is quite distinct from the field of most applied scientific research, the latter being concerned with new or improved processes, equipment, materials, etc.

Let us first look at some of the examples from the Second World War. Operational research was really born out of the 'Battle of Britain'. As is well known, we had in 1940 relatively few fighter aircraft compared with the number that would have been required to defend our shores against an air invader. We had very good fighter pilots and very good aircraft; but, with the equipment and methods used prior to 1940, it would have been impossible to obtain sufficient interceptions to defend our shores. The most important new feature that came in was, of course, radar. This equipment, by giving ample warning, permitted the retention of aircraft on the ground until needed, and then, by plotting the positions of the enemy and defending aircraft, enabled a 'ground control' to direct the aircraft to a position where the enemy could be sighted visually. The planning of this sequence of operations involved careful analysis of training and of operational experiences, and involved also a full analysis of the technical possibilities of the equipment. But the process of combining these factors required mathematical calculations beyond the experiences of the ordinary commanding officer. Accordingly, a small party of half a dozen scientists was attached to Fighter Command, to study and refine the deployment and the operational orders. These scientists learnt how to estimate which were the bad targets and which were the good, and to determine where and how our limited effort could best be expended. Their analyses formed the basis for the operation of the whole defence organisation of Britain. It is estimated that radar itself increased the probability of interception by a factor of about 10; but that, in addition, this small operational research team increased the probability by a further factor of about 2, which together meant that the Air Force was made twenty times more powerful. The operational research contribution, a doubling, was out of all proportion to the amount of effort spent on the research.

An even more startling case was the introduction of Coastal Command to the Battle of the Atlantic. While Coastal Command had a number of successes in the early days of the War, these fell far short of what was needed when the U-boat campaign was renewed with increased intensity during the winter of 1941–42. Prof. P. M. S. Blackett[4], whose name will go down in the history of operational research as outstanding, came into the picture to see what could be done. He built up a small team of scientists at Coastal Command to study all aspects of the problem of air attack on U-boats. Of particular importance was the work of the late Prof. E. J. Williams, who, in the spring of 1941, analysed the previous attacks on U-boats by Coastal Command aircraft. This analysis led to the conclusion that, instead of the depth-charges or bombs being dropped more or less on and about the centre of the targets, there was a serious and not obvious fault in the tactics adopted. Indeed, it later came out that the chances of a successful kill were something like one in a thousand.

The tactics accepted at that time were based on a belief that the best setting for a depth-charge to explode was 100 ft., where the charge would be well 'tamped' by the water. It was also known that when a U-boat dived, it increased its depth at the rate of about 2 ft. a second, and that accordingly it should have been submerged for at least 40 sec. before the depth-charge exploded. (The lethal range of a depth-charge is about 20 ft.) Allowing for the speed of descent of the depth-charge and the forward movement of the submarine, the best time and place to drop the depth-charge could be calculated, using as a point of reference the swirl left by the submerging U-boat. To carry out the attack properly, it would commonly be necessary for the aircraft to frighten the U-boat into submerging and then attack at the appropriate number of seconds later. (In fact, of course, most aircraft went straight into the attack.)

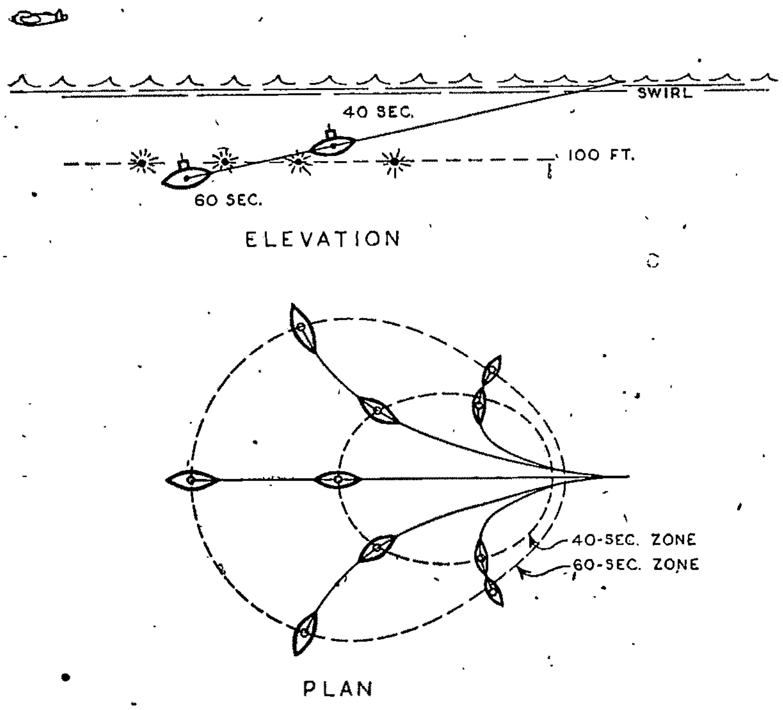
Prof. Williams' analysis showed, among other things, the following statistics (see ref. 4) for the number of U-boats visible and having submerged for different times at the moment of attack:

Condition of U-boat	Percentage of all attacks
U-boats visible	34
Submerged up to 15 sec.	27
,, 15 to 30 ,,	15
,, 30 to 60 ,,	12
,, more than 60 sec.	11

From this it is seen that only about one-tenth of the U-boats could be in the depth-range of the exploding depth-charge, when set to explode at 100 ft. The analysis further showed that the volume of the 'probability zone' in which the submarine lay increased very rapidly, indeed, according to the third or fourth power, with the time of submergence. (See accompanying diagram.) This three-dimensional probability zone is that inside which it is almost certain (that is, 97 per cent probable) that the submarine will be found and is calculated by allowing for all possible movements of the submarine inside the limits of its estimated course and speed, turning circle, etc. The inaccuracy with which the depth-charges were dropped also increased very rapidly with the time of submergence, largely due to the disappearance of the swirl. Taking the two together, it was found that, of the one-tenth of the U-boats which were within the lethal range for depth, fewer than one in a hundred were within the lethal range for plan. By setting our depth-charges at 100 ft. we were failing to engage the targets which could be attacked most accurately and which were by far the most frequent, that is, U-boats visible or submerged up to 15 sec., simply to gain the small increase in lethal range of a depth-charge at 100 ft. This is probably as serious an example as we could have of the concentration on bad targets and the disregarding of good. It is difficult to appreciate how it can have arisen until one realizes how ingrained and over-emphasized certain technical facts on underwater explosions had become. In fact, the change to the shallowest possible depth setting was opposed by a number of technical people, until they were shown the full analysis giving the other aspects of the problem. (This case also showed up a good lesson in research management. In accordance with the procedure at that time still prevailing in this section of the Admiralty organisation, orders were passed to the research station concerned to make the necessary alterations in design. The delay which followed led to a visit of inquiry which elucidated the situation described above. When the research people concerned were finally convinced, the 'unsurmountable' difficulties were resolved in a week.)

To conclude this story, within a very short time of the change being made, first to 35 ft. and later to 20 ft. depth setting, one U-boat was sunk and another captured and brought into port, the only enemy submarine captured during the War. The sinkings went up steadily until a year later they reached twenty a month. The Germans within the first month announced to their Navy that we had introduced a new and much more powerful depth-charge. This change brought Coastal Command effectively into the War, and their aircraft, together with the sea-borne forces, with which they were closely integrated, averted defeat in the most critical period of the U-boat war.

My third story has a somewhat amusing side. During the latter phase of the U-boat war, the enemy U-boats in the Bay of Biscay were countering our radar with some success by listening to the transmissions from our aircraft, and diving at the appropriate moment before we could pick up the radar echo. We countered this by special technical devices and managed to maintain a certain low rate of successes against the enemy. The operational research team of Coastal Command showed, by careful statistical analysis followed by model exercises on a games board, that a saturation technique was possible which would take advantage of the fact that the U-boats' storage batteries would not permit submergence for more than four hours, during which time they would move a certain maximum distance. With the required number of aircraft working in accordance with a definite plan of patrol, there would always be an aircraft inside the critical listening range when the U-boat surfaced, and the latter would be forced to submerge before it could properly recharge its batteries. We would thus exhaust our opponent and he would be forced to stay on the surface. Our sightings would increase to about twenty per week, and as we were getting about one kill in every ten sightings, this would mean about two kills a week. The required number of aircraft was twenty-five more than were available for this patrol force, and a considerable argument with Bomber Command followed a request for the additional aircraft. In this argument, a senior Bomber Command officer inquired whether this War was to be fought with slide-rules or weapons. However, a three weeks trial of the full operation was ordered by the Prime Minister, resulting in sixty-seven sightings and six kills. An extraordinary coincidence perhaps; but the 'slide-rule' had won!



METHODS OF OPERATIONAL RESEARCH

Statistical Analysis

The foregoing examples are obviously very important ones, but they are rather too complex to illustrate methods of operational research. For this purpose a different approach is necessary. In most problems, there are a number of variables to be considered. Our first object is to find the correlation between these variables, our second to test the stability of this correlation by finding the causal link lying behind it, and our final object is to estimate the likely consequences of any particular change that may be imposed upon the system. We thus provide ourselves with a quantitative basis for any decision to be made regarding the change. For example, how does the number of ships sunk in a convoy depend upon the speed of the convoy ? Is the speed the direct cause of the effect ? How many ships are likely to be saved if the speed is increased ? What will be the cost resulting from the elimination or re-routeing of slow ships, etc. ?

Unfortunately, most problems have many variables, which are varying in apparently quite unco-ordinated ways. In addition, there are often superimposed completely random fluctuations, which tend to obscure the correlations. One generally attacks a problem first by a study of past experiences ; if one is lucky, it might be possible later to organise an experiment to test some particular point. The data from these experiences are subjected to a statistical analysis to determine the *intensity* of the correlation between any pair of variables. Are the higher sinkings more frequently found to occur with slow speeds of convoys than with fast ? (The answer, during the War, was found to be 'Yes'.) The intensity of this correlation is expressed quantitatively by the 'correlation coefficient' determined from the statistical analysis.

If a correlation is found, the next step is to find the form of the relation between the two variables. Statisticians call this the 'regression' of one variable on the other. More specifically here we want to know the partial differential coefficient relating the change in sinkings to a change in speed, the other factors, such as size of convoy, air and sea protection, route, etc., being constant or accounted for.

The causal link is best determined from theoretical or other independent grounds. The speed of the convoy is clearly an independent variable, but it may be that the correlated rate of sinkings really depends on some other variable itself accidentally intensely correlated to the speed. For example, the ships might make smoke when steaming at slower speeds and thus be detected by a U-boat at a longer range. However, a study of the performance of the enemy's submarines and of his tactics showed clearly a direct causal link. It was possible to go further and predict approximately the relation between sinkings and speed, and this relation was found to agree satisfactorily with the operational data. It could, therefore, be predicted that, if it was decided to make a certain increase in the speed of convoys, a certain increased safety was to be expected. The loss due to various dislocations of convoy routine was separately calculated and set against the gain, and the net result formed the basis for decisions to increase speed in many important convoys.

Models and Experiments

As will be seen from many of the examples in this article, one of the commonest methods of operational research involves setting up one or more possible imaginary models, studying their expected characteristics and seeing which fits the data best. This is exactly the technique used in the determination of crystal structure by means of X-rays. It is impossible to deduce the structure from the data on X-ray diffraction—the mathematical equations cannot be solved in that direction. One can, however, very accurately calculate the diffraction angles and intensities for a given model or series of models derived from other considerations and be satisfied that only the correct model will lead to data which fit the observations.

Similarly, one can make use of analogies, particularly electrical analogies, as is done so commonly in various branches of physics and engineering.

The use of direct experiments to test a particular point is, needless to say, of the greatest value, but experiments often involve considerable cost. As operational research becomes more accepted, experimental operations will become more common, which in turn will add to the strength of this branch of science.

Sampling and Significance

Full technical details of this important subject can be found in standard text-books such as that by Davies[5]. The relative advantages and weaknesses of different methods of sampling are well known and the reliability or significance of a conclusion from a particular group of data can be determined by standard statistical methods. If certain returns show variations from week to week, a statistical analysis can show what is the chance that differences, equal to or greater than those actually observed, could have arisen from random fluctuations. If the odds against are high, it can reasonably be assumed that some extraneous factor is present; highest odds being necessary where a wrong decision would involve serious consequences.

The significance of a conclusion is greater (that is, the odds are higher) the greater the number of data in relation to the number of variables. The experiences of the War, however, have shown that one should not be deterred from attacking a problem even with only very limited data, particularly when the problem is an urgent one; that is, the risks of delay may be greater than the risk of a decision based on low significance. Very often parts of the picture can be filled in by theoretical deductions and thus one might narrow down the apparent fluctuations and thus effectively increase the significance. In this way, operational research or applied statistics, whichever one cares to call it, departs from or goes beyond the more rigid field of pure statistics.

For example, supposing that over a period of time and in a given area or business there is an average of 500 events per week. If each one of these events were completely independent of one another and of any common factor (that is, they occurred at random, such as is nearly the case with births, accidents, placing of orders, etc), then the odds are fifty-fifty that any particular week would show less than 485 or more than 515 events. In other words, if a week showed, say, 484 events, it does not really mean that the 'orders have fallen' or the 'accidents have fallen', as one commonly sees reported. It *may* be true, but no decision should be based in any way on an isolated fact of this kind.

On the other hand, in a case where the events are the completion of operations in a production line, and where the time of beginning one operation depends primarily only on the end of the previous operation, a weekly return of less than 485 events would be of great significance and extraneous factors should be sought. The significance, therefore, depends not only on the statistical data, size of sample, etc., but also on the expectations of the 'standard deviation' based on an analysis of the technical characteristics of the processes involved.

This question of significance of observations is one of the most important to executive decisions. Probably more wrong decisions arise from an over-emphasis being placed on chance happenings than from any other cause.

Soundness of Data

Before going on to further methods of operational research, some remarks on data are necessary. It is obvious that the soundness of data should be thoroughly tested before the data are used. Hearsay evidence is extremely dangerous. Two examples will illustrate the mistakes that might arise.

In 1940, we were asked at the Admiralty to re-design a certain weapon to enable it to fire vertically. When interrogated, crews of ships attacked by enemy dive-bombers were almost unanimous in saying that the dive-bombers came down vertically. By placing an inconspicuous grid on the wall of the interrogation room and asking the witness to point his hand in the direction of the aircraft, it was soon found that 'vertical' to a man being attacked was between 45° and 75°. This research saved us the task of overcoming very difficult design problems to produce a weapon which would have been of little value.

A similar incident took place with regard to the depth setting of ship-borne depth-charges. Reports from ships at sea continually stated that the enemy submarines went deep and below the deepest setting on the depth-charge. In fact, figures were quoted to support the claim. The statement was suspect because there is a natural tendency in a man, who has carried out an attack accurately so far as he can see, to blame the one factor he could not control, in this case the depth below the deepest setting. Fortunately, it was possible to get an approximate idea of the depth of the enemy submarine by the range at which the asdic beam lost contact, the angle of the lower edge of the beam being known very approximately. This gave a fairly reliable knowledge of the depths of submarines during attacks and showed that very few, if any, were going anywhere near the depths alleged.

The remainder of this story tells of a failure to apply operational research results. The myth that enemy submarines went deep, based at first on human weakness but kept up by intelligence reports from German sources, resulted in an extensive wastage of depth-charges and the escape of many German submarines.

Probability Calculations

The example of the gun just quoted is an interesting one to illustrate a common type of problem. A gun with its sights can be designed to be at its best at a certain angle of fire, its effectiveness falling away on either side of this angle. The usual requirements ask for a gun to have the maximum probability of shooting down enemy aircraft and at the same time to be able to engage an aircraft no matter at what angle it may be. A study of this problem shows that the two requirements are conflicting, and one must choose between the two or compromise. From an analysis of attacks carried out both by enemy aircraft and our own, it was fairly easy to determine the approximate shape of the curve relating the probability, $Q_t d\alpha$, of finding a target at a given angle α (that is, between α and $\alpha + d\alpha$) above the horizontal as a function of that angle. In a similar way, one can determine the probability of hitting, P_h, as a function of the angle. One can determine the overall probability by integrating the product:

$$P = \int_{\alpha}^{\pi/2} Q_t P_h d\alpha.$$

The integral will have its highest value under the conditions where the highest values of P_h coincide with the highest values of Q_t; the contribution to the integral of a region where P_h might be high and Q_t low would be negligible. In other words, the gun should be designed to be most effective at those angles where targets are most probably to be found, and other angles should take second place or be ignored. In this example, Q_t is very low at 90° elevation and so, indeed, in almost any design of gun, is P_h. The complications of designing to cover 90° elevation, particularly as this would lead to reduced effectiveness of the gun at other angles, would reduce the value of the weapon. (In this example, the effects of range, enemy speed, etc., would be roughly included in Q_t and P_h, but in more precise work double or triple integration would be required.)

This is a common problem where coincidences are required. In general, where the requirement is to get the maximum number of hits, we want the integral of the products of the various probabilities to be a maximum, and for this we want the maximum amount of overlapping of the probability curves. We have already seen an important but more complicated example, that of depth-charges used by Coastal Command aircraft. Here, however, the mathematics by the integration method would be too complex and it is necessary to use more approximate methods, in which the submarine is assumed to lie with uniform probability inside a circular or oval-shaped zone. The size of the zone is, of course, a marked function of time; if it is a three-dimensional zone its volume may go up as the fourth or fifth power of the time.

A further example of this type was found in the case of Coastal Forces' counter-attacks on raiding enemy E-boats. The E-boats were first spotted and plotted by radar and the motor gun boats were sent out to attack. As in the case of Fighter Command, the gun-boats were controlled as near as possible to the position of the enemy and if a sighting occurred the enemy was attacked. Most of the E-boat sorties took place in weather of low visibility, which, of course, made our counter-offensive much more difficult.

There was, however, a marked difference between the percentages of sightings obtained by the flotillas of two separate Commands, and a study was made by the naval officers concerned to find the cause. It was appreciated that up-to-the-minute information was important, but it was found that the average time between the obtaining of the position of the enemy and the passing and re-plotting of this position on the charts of the gun-boat was the same for the two Commands. In other words, there appeared to be no statistical difference between the times of the two flotillas. However, the average taken was a linear average, whereas the probability of interception is a function of the inverse third or fourth power of the time. Therefore, the average taken should have been of the times raised to the third or fourth power rather than to the first. When this was done, there was a marked difference found in the averages of the two flotillas, quite sufficient to account for the difference in success.

In other words, there were big fluctuations in the times of transmission. In the successful flotilla, there were fortunately quite frequently a number of short times of transmission and these were responsible for most of the interceptions. In the other flotilla, while the average time was the same, there were fewer exceptionally short times. This fact was not obvious in view of the large random factor involved in the interception problems.

These are examples in which common sense, by applying the scientific method, has been turned into quantitative common sense.

Causal Links

A discussion of causal links is liable to lead one into the realms of philosophy or at least into difficulties as to the meaning of cause and effect. However, there are many branches of science in which there is no ambiguity and in these one can predict with a high degree of certainty that if certain things are done, a known effect will follow; for example, a force can *cause* a movement. As one of the primary objects of operational research is to predict the future, it is necessary to find some assurance that a particular relation between two variables is a stable one. If the data go back some time and have consistently supported the relation, then stability can probably be safely assumed, but the best basis for security lies in an accurate knowledge of the causal link behind the empirical relation. With such a knowledge, it is possible to use data collected over a shorter time and to make all conclusions of much wider and more general application.

It has already been emphasized that statistical correlation between two variables gives no indication of a causal link. Indeed, the history of applied statistics is full of examples where inexperienced people have jumped to conclusions in this connexion. For example, during the War a graphical correlation between the numbers of pilots having various degrees of 'night vision' and the successes of pilots in intercepting enemy aircraft at night was taken to prove the importance of 'night vision' (the tests actually included intelligence and quickness of response as well). A closer scrutiny of the results, however, showed that the predominant factor was the distribution of pilots over the various degrees of night vision, and the coincidence of the maxima of the two curves at 'degree 22' merely showed that the successful night fighters had the same *average* night vision as the bulk of the pilots.

It is well accepted in the iron-making industry that the output of a blast furnace falls if the conditions are changed to produce iron with a higher silicon content. This, indeed, can be proved very clearly from statistical data. The real cause here, however, lies first in the fact that higher silicon iron requires a higher temperature to shift the equilibrium towards the reduction of silicon dioxide, and the blast furnace would require more coke and more air in relation to the iron produced. Blast furnaces are designed, however, to operate with a more or less fixed maximum quantity of air and, therefore, the output falls, simply because in practice the furnace cannot get more air. There is thus no direct causal link between output and silicon content. A furnace to give a fixed through-put of iron could be built, but it would require a different design.

Organisation of Operational Research

Operational research may be carried out in two ways: either as part of ordinary research work or in a separate section set up for the purpose. Each of these has its protagonists. Clearly, a man who undertakes the research and development leading to a new piece of equipment or a new process should learn for himself the many operational problems concerned therewith. He should also follow up his new equipment or process by studying its behaviour in actual use. This might or might not be called 'operational research' according to the use made of the methods outlined in this paper.

On the other hand, there are severe limitations on this latter type of organisation, limitations which can largely be overcome by the setting up of a separate section. If operational research is to provide executive departments or managers with a quantitative basis for decisions, the men carrying out the research must be in the closest possible contact with the men who make the decisions; the value of their advice will be directly related to the extent to which they can see the overall picture of the problem under consideration.

A second advantage of a separate section is that it frees the operational research workers from executive responsibility. They are thus able to initiate studies with greater freedom and are limited only by the confidence that can be built up between themselves and their colleagues. Executive responsibility, whether in a normal research department or in management, has not been found conducive to the best operational research, and most of the successes of this work have been associated with 'free lance' teams. On the other hand, operational research teams should, of course, have a good sense of responsibility towards their task and their employers; but, as 'common sense' is one of the first qualifications of an operational research worker, no difficulty should be found in practice. A full discussion of the organisation of operational research must, however, await further peace-time experience.

PRESENT AND FUTURE OF OPERATIONAL RESEARCH

Application to Traffic Problems

The extension of operational research in peace-time activities is already in full swing, particularly in certain specific branches. Some of the most interesting recent applications have been in the fields of railway and road traffic. Both fields give a promise of useful results on the application of the scientific method.

One of the principal railways of Britain, the former L.M.S., has set up a special research unit attached to the operational side of the railway, and this unit has already completed thorough studies of some parts of the communications system, on which the effective running of a railway so much depends. These investigations have shown quantitatively where delays more commonly occur and have also predicted the likely improvement and saving that would result from certain possible changes in organisation and equipment. Those changes which show good returns are now being made. Needless to say, studies are also being made in the delays in the operation of the trains.

The road problem has two sides, the reduction of accidents and the improvement in flow. Losses due to accidents or delays on the roads to-day represent a serious loss to our national income or productivity. The Road Research Board of the Department of Scientific and Industrial Research has set up a strong team to study the problems involved. A wide range of the tools of modern science are at their disposal, a major one being the statistical method.

There are many problems in this field. For example, studies are being made of the factors affecting the usefulness of a typical road junction as controlled, say, by traffic lights. From a flow aspect, the main object is to get through the maximum number of vehicles and pedestrians with the shortest delay for each. From a road safety point of view, the object is to reduce the probability of an accident, and particularly of a serious accident, to the lowest possible value. These two objectives are to some extent conflicting, but the extent of the conflict may be very considerably reduced by studying all the factors associated with the junction and with its use. In other words, it should be possible to increase the flow-rate and reduce the danger of accidents at the same time. The way to do this can best be found by a close study of the operations of the various factors involved. A statistical study can be made of a number of road junctions of the same type and loading. However, there are severe limitations here because of the wide variations in type and loading, etc., and because of the fact that the frequency of accidents at each junction is low. It is necessary to deduce the relation between any two parameters from first principles, testing these relations where possible against such reliable statistics as may exist. These first principles are derived from studies of human reaction time, of the braking and manœuvring power of vehicles, of the conditions of the surfaces and the lay-out of the roads, of the timing and other characteristics of controlling lights, etc. Studies of this kind have, indeed, gone on for many years. As a result, London, for example, has one of the most highly developed and successful traffic signalling systems in the world. However, the development of this system is far from complete, but having been carried so far, much more powerful methods are now required to make further progress.

Most of the data in this field of traffic flow and accidents have been collected from studies of daily operations, with their associated mixture of variables, or by taking advantage of some change brought about for other reasons. In this field, however, changes introduced primarily to help disentangle data, that is, 'experimental operations', hold out great promise and, indeed, are already being tried.

There is one general point of technique worth referring to in connexion with this field. For example, it may be required to test experimentally the effect on a dependent variable, such as traffic flow rate, of increasing a given parameter, such as the width of a road section. The cost of increasing the width experimentally would be prohibitive, but a good approximation to the value of the partial differential coefficient in the neighbourhood of that particular road width can sometimes be obtained by experimentally *decreasing* the width of that section. This technique is based solely on the assumption, frequently a reasonable one, that the curve showing the relation between the two variables is a smooth one. The function need not be linear, but there should be no marked discontinuity or excessive curvature in the region considered.

There are also similar traffic problems more directly in industry. For example, the cost of transporting the fuel and raw materials and the products of the furnaces in an iron and steel works amounts to a large item in the cost of steel. This arises not only from the direct cost of traffic but also from hold-ups of parts of the plant awaiting materials, etc., or from more subtle points such as the need for close schedules. A full operational research into the details of this problem is now being made as a necessary preliminary to the engineering lay-out and design problems involved in improvements.

Application to Productivity and Output

Time and motion studies of operators of machines or of workers making repetitive operations have for long been one of the main research methods of the production engineer and the 'industrial consultant'. This method is steadily being improved and strengthened, recently by the exchange of lessons between this and other methods of operational research.

Extensive studies of productivity and of its reciprocal, O.H.P. (operator hours per unit of production) have been made by Tippett[6]. The factors governing O.H.P. in the factories of the cotton industry have, to a large extent, been resolved from a mass of data collected over a number of years. Decisions concerned with productivity by the management of individual firms, or policy decisions by Government Departments, are generally made with the results of these studies as a basis.

Similar studies have also been made of the processes occurring in chemical plant; but it is doubtful whether this should be called 'operational research'. It is probably better to consider this work as part of the normal type of research required to develop or improve existing processes.

Application to Inspection and Maintenance

Inspection has long been a field for the successful application of statistics; 'quality control' is now accepted practice with many large manufacturers. As an interesting example of a rather special type, an inquiry has recently been made into the distribution of the inspection effort in a steel works. In accordance with common practice, the inspection was made on a certain finished article at the end of a series of operations starting with the raw steel billet. Rejects at this final stage were, however, costly and the question arose: Could the faults leading to rejects be reliably detected at an earlier stage? A close statistical analysis, coupled with certain trial runs, showed that this was possible for several of the major types of faults, and the cost of the rejects has now been reduced to less than half without in any way lowering the standard. Furthermore, it was found possible to eliminate certain of the final inspection tests as they were now covered by the earlier tests, and hence the total inspection effort was not increased. The research here led to no new equipment or process, but merely to a re-deployment of inspection effort.

Good examples of operational research applied to maintenance problems in industry are not known to me and therefore I am tempted to return to one of the most striking examples of the War, the studies made by Dr. C. Gordon, in 1942–43, on the maintenance of aircraft, some details of which are given in "Science at War" (p. 104)[7]. These studies of the occurrence of faults in aircraft as a function of maintenance showed that it was possible to increase the flying hours at the expense of the hours an aircraft spent undergoing maintenance without any appreciable increase in the number of faults. As a result, the rigid schedules of maintenance were altered, with a very substantial increase in our fighting strength.

An obvious example where operational research is needed to-day lies in the maintenance of road traffic signals. It appears that the cost to the community of faulty signals and of maintenance is wrongly balanced. In the aircraft example, maintenance was overdone, whereas in this example, it appears to be underdone. It seems likely that operational research methods can be of great use to the maintenance engineer.

Application to Technical Progress

The change in public attitude to science in recent years has led to the question: Why is there such a long interval between the discovery of a new scientific fact and its application to the benefit of mankind? The answer to this would in itself require a lengthy research, but one factor is of obvious importance. A decision to try an idea out, when made reasonably, is based on a weighing of the pros and cons, many of which concern costs in money, coal or man-power. If it is not possible to weigh these sufficiently accurately to see which is the greater, a decision is naturally postponed or made on a 'hunch'. If operational research is successful in providing a quantitative basis for decisions, it should be able to shorten the interval between discovery and application.

There is, however, a danger here that operational research will be diverted to the routine task of 'vetting' inventions which arise through the initiative of individuals driven by parental interest. Operational research workers should be able to take a wider view of a problem, study its economics and its technicalities as a whole and, as a result, see how a proposed change or invention would affect the problem.

In certain research associations, such as that for iron and steel, operational research is already playing a major part in the formulation of programmes of applied or objective research by providing a logical basis for deciding what is worth while developing through its later stages.

Operational research is also playing a part in following up technical progress. The Ministry of Agriculture analyses regularly how far the knowledge of scientific research is being applied by farmers and thus obtains a basis for part of its educational and control schemes.

Future Trends

While there were certain technical developments in regard to the methods of operational research during the War, it is likely that these methods will be developed very much further. The application of the statistical tool is still on the increase, but there is no need or likelihood of the tool itself being developed further. There are many other tools in science, however, which will be tried, and some of which we hope will be successful.

One of the most important of these is the general concept of forces, potentials and equilibria in relation to the Second Law of Thermodynamics. This Law may be expressed in a general form as follows: If there is any 'tendency' for a certain thing to happen, or if a process is potentially able to take place in a certain direction, it should be possible to harness that process to produce external work, the amount of which per unit of process is a measure of the 'tendency'. In certain cases the tendency may be realized as a force.

The generalized Second Law of Thermodynamics should be capable of wider application despite the fact that one cannot take advantage of the rigorous relation between force and work found in the physical sciences. One of the most important forces in sociological systems is that of incentive. If an individual or a group of individuals does something in a certain direction, then there must be a force or incentive, the net value of which determines that direction. If we can elucidate and estimate the various components of that force, we can predict the behaviour of groups of people in given circumstances.

The concept of equilibrium is also capable of wide application, particularly as it can be shown that a system showing an equilibrium position can change only in a direction towards that equilibrium (except under external influence). Furthermore, the amount of the external influence required to keep a system away from its equilibrium rises rapidly with the extent to which it is kept away. For example, the cost of food subsidies rises rapidly as the equilibrium (free economic or supply-and-demand price) departs from the actual fixed price.

We can look forward to the day when the *science* of economics will be sufficiently developed to enable man to gain better control over his circumstances. I believe this science will only grow by the methods of operational research and more specifically by developing its own versions of the First and Second Laws of Thermodynamics, the First being the law of conservation of equivalence, the Second the law of direction of changes as governed by (economic) forces and of the associated conditions of equilibria.

Self-compensating and Self-aggravating Systems

This last point about equilibria leads to a further point. Practically all processes occurring in physical or natural science can be divided up into two categories, those which are self-compensating and those which are self-aggravating. The first are those described by the well-known theorem of Le Chatelier. 'If a change is imposed on a physical system in equilibrium, there are automatically generated other changes which tend to offset the effect of the first change.' This theorem follows from the Second Law of Thermodynamics and is of general application.

In contrast, self-aggravating systems are those in which a small change leads to a further change which *enhances* the effect. In the extreme cases, the result is catastrophic. In others, the enhancement proceeds until other self-compensating or attenuating factors present bring the situation under control and possibly reverse the direction of the change. Such systems generally lead to vigorous oscillation.

There are many examples of each type of system in the ordinary operations concerned with our daily life. Of the first type, there is the example of the reduction of the blindness of a blind corner. Such a change should normally result in a reduction of the number of accidents at that corner, or at least the danger of an accident. As, however, it would be followed by an automatic increase in speed of the cars taking that corner (as a consequence of the greater security felt by the drivers), the net reduction of the danger will be less than would otherwise be expected. This simply means that danger and speed are in equilibrium.

A good example of the self-aggravating type concerns the movement of buses. Consider a system in which buses depart at regular two-minute intervals from a depot and pass along a route through a large town to another depot. Under normal loading and with no special obstacles, the two-minute interval can be retained fairly accurately throughout the entire schedule. If, however, a small delay takes place with one bus when the load is near the maximum designed value, this bus will then find itself faced with the problem of picking up a larger number of accumulated passengers than it would otherwise have had to do. This immediately adds further delays which further aggravate the loading on this particular bus. This, of course, is the basic cause of the 'convoys' of buses which form rather frequently in large towns such as London.

A very similar problem is found in connexion with the supply and demand of scarcity goods. On first thought, it might be assumed that a system, in which there was an even flow of cigarettes from the manufacturers to the shops and an even rate of smoking, would be one of stability. Indeed, in normal conditions when there is no thought of scarcity, it is. The stocks held in retailers' shops provide a reserve or buffer for fluctuations in demand. The ordinary person becomes used to the fact that he can buy cigarettes on demand and therefore it is not necessary for him to maintain a large stock of his own.

Under conditions of scarcity, however, the stocks of a retailer are considerably reduced and the stocks of the consumer are increased because of his bitter experiences in being refused. The situation fluctuates widely because should there be, by some initial fluctuation, a small deterioration in the supply position, a consumer's reaction is immediately further to build up his own stocks. This in turn aggravates the retailers' stock position and induces other consumers to take corresponding self-protective action. Thus a small decrease in the available supplies in shops can quickly lead to a complete emptying of the shops; a rumour can become a reality.

I once had the opportunity of studying a similar self-contained system. The supply of chemical apparatus from a college 'loan store' would collapse annually at a certain time due to a self-aggravating factor of this type. The collapse was preceded by a sudden falling off of returns of apparatus after use, the falling off in turn being due to the beginnings of non-availability of certain items. There are numerous other examples, such as a run on a bank or the locking of a traffic roundabout due to some small initial fluctuation when it is near its maximum loading point. The economic trade cycles are presumably kept in oscillation by self-aggravating factors of this type.

The method of combating self-aggravating systems by the damping effects of controls and reserves is also well known. This method is parallel to the use of resistances and condensers in electric circuits. Operational research can lead to more exact knowledge of these systems to enable a better balance between reserves and flow and a better phasing or timing of actions intended to damp down or offset an impending change. One of the greatest problems for the Government administration has been to obtain 'early warning' of a particular situation and thus to avoid the more drastic compensating action required if the problem is left until it has built itself up to a serious state.

Conclusion

The arguments in this paper are based partly on the experiences of War and partly on those of two and a half years of peace. There are obviously many differences between the two conditions. War leads to a great degree of centralization of control and consequently a lack of flexibility. This is a situation in which operational research is potentially able to produce enormous improvements, partly because in certain respects it is a situation full of weaknesses to start with. On the other hand, an industry consists of a number of units or firms each evolving its own methods and working independently. Accordingly, variations of working methods occur, if only by chance. In normal economic conditions, the variations of positive value will have a greater chance of survival than those of negative value. In other words, 'natural selection' can operate in the uncentralized systems, providing there is a freely competitive economic system operating. As a result, it might be argued that operational research would be less likely to make such startling improvements in peace as it did in war. However, the same is true for applied science in general: the results in war are much more startling than in peace-time.

History has shown that results in war are followed by extended application in peace-time, and the case of operational research is so far no exception. This technique is becoming a new tool for executives, alongside their older tool, accountancy. It is a tool that the executive man can readily understand; it is not wrapt in the 'mysteries of science'. For him, his business life is becoming more and more complex as the repercussions of any one act or decision become wider. As a result, the waste of time in arguing with 'half-truths' becomes more serious. We are entering an age of statistics collected with great consumption of man-power. The new methods of operational research are needed if these statistics are not simply to add to the half-truths but to play their proper part in the more highly developed thinking processes now required.

PROGRESS OF CANCER RESEARCH

By Dr. I. HIEGER
Chester Beatty Research Institute, Royal Cancer Hospital, London

THE composition of the twenty-fourth annual report of the British Empire Cancer Campaign (11 Grosvenor Crescent, London, S.W.1) shows that more research is being carried out on radiation therapy and theory, on carcinogenesis and on the biochemistry of cancer, than on any other branch of investigation pursued in the different centres of research supported by the Campaign.

It is of interest to see to what extent the subjects of study are representative of cancer research in other parts of the world by a comparison with the papers presented at the Fourth International Cancer Congress held at St. Louis last September. More than 75 per cent of the 260 odd papers given at the Congress were by scientific men from the United States, and it should be noted that their papers tended to be finished products, whereas the Campaign's report is rather more a statement of progress. Any such comparison is certainly liable to errors, for a number of reasons; nevertheless, the accompanying table will probably give an approximate idea of the relative precedence of the different lines of research with which the cancer problem is attacked.

	4th International Cancer Congress, 1947	B.E.C.C. Report, 1947
Radiation therapy and theory; use of radio-isotopes	35	18
Biochemistry of tumours and tumour bearers; nutrition; enzymes; nucleoproteins	33	12
Carcinogens, carcinogenesis	32	13
Chemotherapy	32	7
Pathology and diagnosis	25	5
Hormones in cancer	20	2
Advances, clinical and surgical	13	5
Organisation (research and clinical)	12	—
Cytology and cytochemistry	11	1
Genetics and mutation	9	2
Comparative oncology	9	—
Tissue culture	8	2
Experimental pathology	8	6
Milk factor	8	1
Virus tumours	5	6
Social, racial and industrial cancer	5	1

Only a few of the interesting investigations described in the Campaign's report can be referred to in this review and some important work will unfortunately receive no mention.

It need scarcely be stated that much essential clinical investigation has been carried out at all medical centres, and an elaborate report of the Clinical Cancer Research Committee analyses nine hundred cases of cancer of the colon from every etiological, pathological and clinical angle.

The increasing prominence of physics in cancer research is chiefly due to developments in the technique and theory of radiotherapy, in the use of radioactive isotopes, in the field of microscopy and in the application of physical chemistry to the study of carcinogens. The electronic characteristics and structural properties of carcinogens are now being used to explain why some compounds are carcinogenic and others not.

Haddow, at the Royal Cancer Hospital, recently arranged a meeting which Dr. Pullman from Paris was invited to address on a theory of electronic characteristics and carcinogenic activity of hydrocarbons. At this discussion, Dickens neatly hit the nail on the head by pointing out that the proof of any such theory would be its capacity to predict the structural requirements for a 'super-carcinogen'.

If the emphasis at the present time is favouring the physicist, the organic chemist has found at least one sphere for new synthetic work, that of chemotherapy, for another class of compounds has been introduced, the nitrogen mustards (for example, methyl-*bis*-(β-chloroethyl) amine). The large number of papers on chemotherapy presented at the International Congress shows how intense is the search for some drug which will selectively destroy cancer cells. The interest in chemotherapy would probably be greater than that suggested by the table if the hormone investigations directed to hormone therapy were included.

Unfortunately, the extreme caution with which therapists are compelled to state their results has a decidedly chilling effect on the reader: for example, they are apt to speak of "some degree of amelioration, although the response is usually transient", or "every case of Hodgkin's disease has shown a good although temporary response to the drug", or "it is doubtful whether any retarding influence has been present in our cases". Research, or rather experimentation, in this field is still highly empirical, dare one say, haphazard; this is inevitable, for we still have very little knowledge of the vulnerability of cancer tissue.

Passey and his collaborators in Leeds are working with the transmissible milk factor for mouse mammary carcinoma, and have elegantly demonstrated by the electron microscope the presence of macromolecular particles of definite size only in those tissues and secretions where the factor has been detected by the biological method. The further progress of these experiments will be awaited with much interest.

The mode of action of carcinogens is claiming more attention, to the satisfaction of those who see little purpose in the continued multiplication of new synthetic carcinogens. Selbie, at the Middlesex Hospital, and also the Edinburgh workers, have studied carcinogenesis by urethane on the lung of the mouse. They suggest that some tissue is stimulated to proliferation at a rate disturbing to tissue equilibrium, and that the urethane poisons a defence mechanism, allowing some other agent, perhaps a virus, to attack the cells and bring about malignancy. It may perhaps be objected that such an explanation scarcely does more than move the difficulties one step farther back.

Orr, at Leeds, comes to somewhat similar conclusions, namely, that the lung adenomata evoked by urethane supervene on an inflammatory process, and that mice, the lungs of which are particularly liable to pneumonic conditions when treated with urethane, are also more liable to lung tumours.

Dickens has succeeded in showing that saturated compounds can be dehydrogenated to the aromatic state by rabbit blood and by slices of muscle, kidney and spleen. The interest of this reaction lies in its bearing on a popular theory of cancer: that polycyclic saturated compounds in the body (cholesterol, sex hormones, bile acids) can by some error of metabolism be dehydrogenated to polycyclic aromatic carcinogens. Similar studies are being made by Shoppee at the Royal Cancer Hospital on the possibility of the conversion of 17 α-methyl-*D*-homoandrostane to carcinogenic methylchrysenes.

Berenblum has been working on the mechanism of the carcinogenic process with the aid of co-carcinogens, and also on the nature of the cancer-producing factors in addition to benzpyrene which are present in tar. This work, and the experiments of Woodhouse at Birmingham on petroleum, might give valuable information if an attempt were made on the part of a government inspectorate to assess the risks of using certain petroleum products. However, any such tests and recommendations would have little effect so long as industrial substances which are carcinogenic are not handled entirely by mechanized processes.

Glücksmann, at Cambridge, has treated mouse tissue with X- and γ-rays in combination with co-carcinogens to see if the same synergistic effect can be observed as with chemical carcinogens. No such effect was detected, and histological examination showed profound differences between the papillomas induced by radiations and those induced by benzpyrene. Also at the Strangeways Laboratory, Lasnitzki has found that when an adenocarcinoma in mice is irradiated with X-rays, two-thirds of the injurious effect on the tumour is indirect and is brought about by changes in the still normal tissue surrounding the tumour. Thus the conclusions of Koller, arrived at by studies on irradiated tumours in human subjects, have been confirmed experimentally.

Peacock, at Glasgow, has investigated the co-carcinogenic action of croton oil added to overheated (365°) edible oil in feeding experiments on mice. He found that cancerous changes were brought about in the alimentary tract, although the proportion of positive results was much smaller than in experiments with carcinogenic hydrocarbons on skin or connective tissues. Similar tests on mice mutants produced by methylcholanthrene (Strong) which are particularly liable to gastric cancer might show facilitation of the effect of feeble carcinogens in the diet.

Pybus and Miller, at Newcastle, and also Carr, at Edinburgh, have been studying gene mutation produced by the administration of carcinogenic hydrocarbons to mice. The mutation theory has had an eventful career in cancer research. One of the first to propose that cancer cells are mutant forms of normal cells was Boveri, in 1912. X-rays and radium had long been known to be carcinogenic, when Muller in 1928 discovered that X-rays greatly increased the spontaneous mutation-rate in *Drosophila*. During the War, Auerbach *et al.* found mustard gas to be a potent mutagen; but unfortunately for the theory, Berenblum had shown that it prevents carcinogenesis by the hydrocarbons. Strong's discoveries have now been followed by a report from Demerec that benzpyrene and other carcinogenic compounds bring about mutations in *Drosophila*. He finds about 84 per cent correspondence between carcinogenic and mutagenic potentiality in a number of compounds given to the fruit fly in the form of a fine mist.

Sir Ernest Kennaway and Lady Kennaway are continuing their statistical work on the Registrar General's returns, and point out that in eighteen years the deaths from cancer of the lung in England and Wales have increased 16½ times in men (nearly 6,000 in 1945) and 8 times in women, although diagnosis must have been doubtful in some cases.

One of the most interesting conclusions in this investigation runs: "Cancer of the lung differs from that of the upper alimentary tract, larynx and skin in showing no inverse relation to ascent in the social scale (Stevenson, 1923). This suggests an airborne factor, as owing to the mixing action of the wind, there is less difference in the outdoor air breathed by different classes than in other social conditions such as food and cleanliness."

Hieger, in experiments on endogenic carcinogens, finds that these substances are concentrated in the cholesterol-rich fraction of tissues, not only from cancerous and non-cancerous human subjects, but also in commercial cholesterol obtained from cattle brain and spinal cord or from fish livers. Some recent results were described in this journal ("Carcinogenic Activity of Preparations Rich in Cholesterol", *Nature*, **160**, 270; 1947).

OBITUARIES

Dr. Bernard S. Dyer

The death of Dr. Bernard Shirley Dyer on February 12, in his ninety-second year, marks the passing of one of the very few remaining pioneers of agricultural chemistry of the late nineties.

Born in London on February 25, 1856, the son of J. A. Dyer, a well-known London journalist, Bernard Dyer was educated at the City of London School. On leaving school at the age of seventeen he became a pupil assistant in the laboratory of Dr. Augustus Voelcker, consulting chemist to the Royal Agricultural Society, spending three years there and later taking the University of London degree of B.Sc. In 1877, at the early age of twenty-one, he established his laboratory at 17 Great Tower Street, London, where he remained until the laboratory was destroyed in the 'blitz' of May 1941. Here, while engaged in building up a practice in agricultural and food chemistry, he devoted much time in his earlier years to the publication of a series of agricultural articles in the scientific and lay Press, and also undertook a very considerable amount of lecturing throughout the country. About this period he was appointed consulting chemist to the Devon Agricultural Society, and later to the Essex and Leicestershire Societies.

There can be little doubt that Bernard Dyer's training with Voelcker had led to a specialization in agricultural chemistry which determined his future trend and the major interest in his life. Year after year, papers were published dealing with field investigation work, and, in particular, with the use and application of fertilizers and the necessity for far larger amounts than was then customary in Britain. Then came some years of work on the vexed question of soil analysis as a means of indicating the availability of the mineral constituents of the soil. The suggestion had already been made by Sachs that plants extracted their mineral food from the soil by the solvent action of the root sap exuded from their root hairs, and Tollens and Stutzer had suggested the use of a 1 per cent solution of citric acid for the assessment of the relative 'availability' of phosphatic fertilizers. Bernard Dyer attacked the problem from this new angle. He first determined in his laboratory the root acidity of about a hundred plants, and found the average figure to be the equivalent of 0·9 per cent citric acid—a figure substantially that suggested by Tollens and Stutzer. He then, in 1889, systematically analysed soil samples from twenty-two plots of Hoos Field, Rothamsted. The outcome of this work was the elaboration of the now well-known method of soil extraction using a 1 per cent citric acid solution. This was published in the *Journal of the Chemical Society* in 1894, and for this investigation the

University of London granted him the degree of D.Sc.

The next years were devoted to the larger task of examining the soils of the historic Broadbalk wheat field, including plots manured and unmanured for fifty years. The results of this work were recorded in 1901 in the *Philosophical Transactions of the Royal Society* in a paper entitled "A Chemical Study of the Phosphoric Acid and Potash Contents of the Wheat Soils of Broadbalk Field, Rothamsted". The paper was published shortly after the death of Sir John Lawes, to whom the inspiration of this particular investigation had been due. Shortly before this, in 1900, Dyer delivered the triennial course of Rothamsted American Lectures at Newhaven, U.S.A., afterwards published by the United States Department of Agriculture under the title of "Results of Investigations of the Rothamsted Soils". In 1893 he published a little book, "Fertilizers and Feeding Stuffs"; and in 1924 a book on "The Manuring of Market Garden Crops", this latter being a record of the results obtained from more than twenty years of field experimental work in Kent.

Turning to his other great activity, Bernard Dyer became an original member of the Society of Public Analysts in 1875, and to the affairs of this Society he gave much of his time, first as a member of council in 1880, and then as joint honorary secretary during 1883–96, when he was elected president in succession to Sir Thomas Stevenson. He contributed many papers to its journal, *The Analyst*, and, in collaboration with Dr. C. Ainsworth Mitchell, prepared its history, "Fifty Years of the Society of Public Analysts". He was elected an associate of the Institute of Chemistry during the year of its formation (1878) and became a fellow in 1880. He was an original member of the Society of Chemical Industry, and acted as chairman of its London Section during 1923–24. He held official appointments as agricultural analyst, as public analyst, and as official analyst to the London Corn Trade Association.

Dyer married twice, first Alice Collett, and secondly in 1890 Edith Steel, who survives with two of their three daughters.

Dr. Bernard Dyer will be remembered by all his friends for his great personal kindliness and charm. As a member of many societies, he was greatly esteemed by his colleagues and held in the greatest affection by his juniors, who remember his kindly help in their struggling years. As an analyst he was austere in the conception of his duty in seeking the truth.

G. TAYLOR

WE regret to announce the following deaths:

Mr. Griffith Brewer, president during 1940–42 of the Royal Aeronautical Society, and a pioneer of aeronautics in Great Britain, on March 1, aged eighty.

Prof. R. T. Chamberlin, emeritus professor of geology in the University of Chicago, aged sixty-six.

Dr. A. L. Du Toit, F.R.S., lately consulting geologist to the De Beers Consolidated Mines, on February 25, aged sixty-nine.

Mr. G. S. W. Marlow, secretary of the Faraday Society, on March 5.

Sir Charles Grant Robertson, C.V.O., principal and vice-chancellor of the University of Birmingham, on February 28, aged seventy-eight.

NEWS and VIEWS

Radio Research in Great Britain:

Dr. R. L. Smith-Rose

IN 1920 the Department of Scientific and Industrial Research, guided by a newly formed Radio Research Board, started research in radio, which had grown in importance during the First World War. Most of the work was done at a field station at Slough under R. A. (now Sir Robert) Watson-Watt, and at the start attention was mainly devoted to investigations on atmospherics, direction-finding and the propagation of waves over the ground. When, in 1924, Appleton and Barnett demonstrated the reflexion of radio waves from the ionosphere, they asked the co-operation of Slough in fundamental experiments which laid the foundations of our present knowledge of the subject. Later, much of this experimental work was transferred to Slough, still under Appleton's guidance, while he continued his own work at Cambridge. In this way there grew up at Slough a team skilled in the use of pulses for the determination of distance by radio methods, which was able to turn its energies to the development of radar when the time came. In 1933 Slough and other radio research stations under the Department of Scientific and Industrial Research had been formed into a Radio Division of the National Physical Laboratory, with Watson-Watt as superintendent. In 1935 he took away a small team of experts to start a secret radar establishment, and Dr. R. L. Smith-Rose succeeded him. Just before, and during, the War, the ionospheric investigations at Slough developed so as to provide a world-wide organisation for the forecasting of propagational conditions on different wave-lengths, and there has, in addition, been considerable work on direction-finding, the propagation of ultra-short waves through the troposphere, the development of *radio sonde*, and the measurement of the electrical properties of soil and water at radio frequencies.

A new arrangement has recently been announced by which it is intended to combine the work at the National Physical Laboratory and Slough and to transfer it to a new establishment under Dr. Smith-Rose as director of radio research. The new establishment will, by this arrangement, have a director who has been personally active in several lines of research. In the early days at Slough he was engaged, with Barfield, in investigations of the propagation of waves over the surface of the earth and in problems of direction-finding. The study of propagation led him to work on the electrical properties of soil and water, and to investigate the forward tilt of waves travelling over the ground; the work on direction-finding led to a clear understanding of the part which the wave deviated by the ionosphere can play in producing errors in a loop direction-finder, and to an explanation of the errors produced by conducting bodies near the loop, the so-called site-errors. He has published papers on the propagation of waves through the troposphere and on improved methods of direction-finding, particularly on very high frequencies. He has been chairman of the Radio Section of the Institution of Electrical Engineers, and was decorated with the United States Medal of Freedom with Silver Palm for his work in radio during the

War. Under Sir Edward Appleton's able guidance, Britain has established a lead in the scientific applications of radio, which the country will look to the new Radio Research Establishment to improve. With the present team under Dr. Smith-Rose, and with Sir Edward at the head of the Department, they are not likely to be disappointed.

Deputy Scientific Adviser to Army Council: Prof. F. J. M. Stratton, O.B.E., F.R.S.

The appointment of Prof. F. J. M. Stratton to the post of deputy scientific adviser to the Army Council has been announced. Prof. Stratton's retirement from the chair of astrophysics at Cambridge last October was announced in *Nature* (**159**, 463; 1947), and the record of his scientific work was noted. His was a retirement dictated by the rules of superannuation, and not by any loss of activity; so that his choice for and acceptance of this further post will be no more a surprise to his friends than his own preference for further service to merited retirement. The War Office is fortunate in securing the services of so able a man of science, particularly one who has given proof, through ten years service in the Army in two wars and a long association with the Cambridge O.T.C. and the Territorial Army, of his aptitude and interest in military affairs. While his appointment will be a temporary one for a limited period, the acquisition to the Scientific Civil Service, even for a short time, of such men as Prof. Stratton will be a source of strength to the Service, and the experience and leadership he can give to some of the younger men of science employed by the Army, in operational research and other tasks, will obviously be of the greatest value to them.

Willard Gibbs Medal: Prof. Carl F. Cori

Prof. Carl F. Cori, professor of biochemistry in the Washington University School of Medicine, has been awarded the 1948 Willard Gibbs Medal of the Chicago Section of the American Chemical Society. This medal, one of America's highest scientific honours, goes to Dr. Cori for his achievements in research on the processes by which the body converts sugar into energy. He has been a leading worker in the difficult field of biological carbohydrate transformations for many years. His contributions have been of widespread importance involving adrenal, cortical, pituitary, and pancreatic roles in carbohydrate utilization as well as carbohydrate metabolism in tumours. A recent outstanding contribution is at least a partial solution of the problem of how insulin functions. He and his wife, Dr. Gerty T. Cori, who is also a professor of biochemistry in Washington University, received the Nobel Prize for Medicine for 1947 (see *Nature*, **160**, 599; 1947) for determining the process by which the body stores sugar in the liver as glycogen, or animal starch, and then reconverts the glycogen to sugar as it is needed.

Library of the Royal Society: Mr. H. W. Robinson

On March 31 Mr. H. W. Robinson retires from the office of librarian of the Royal Society. He joined the staff of the Society in 1902, when as a boy of fourteen he assisted both the chief clerk and the librarian. His work soon became exclusively associated with the Society's Library; in 1930 he was raised from assistant to the post of assistant librarian and five years later to the position which he now holds. This forty-six years service to the Society has been twice broken by war. In the First World War Mr. Robinson served in the army with distinction; in the Second World War there was a period of service on the Central Register, which came between the strenuous work which he performed in seeing the Society's manuscripts and early printed books safely to Wales and his recall to the Society's service in 1943. Since then he has had the exacting but pleasant task of seeing the Library's books brought back from Oxford, where they had been stored by the Bodleian Library, and arranged in their places with a minimum of inconvenience and disturbance.

Mr. Robinson has a unique knowledge of the Society's Library and in particular of its extensive and priceless archives, a knowledge which he has always been delighted to put at the disposal of the scholars, from many countries, to whom his learning is well known. His intimate acquaintance with the Society's traditions and records has found expression in his services to the history of science. He is, for example, an authority on Robert Hooke, having edited, in conjunction with Mr. Walter Adams, the Diary in the possession of the Guildhall Library and having identified as another Diary of Robert Hooke the manuscript in the British Museum previously attributed to James Petiver. With Prof. Harcourt Brown and Dr. D. McKie he founded the *Annals of Science*, and he was actively associated with the foundation of the British Society for the History of Science, of which he is honorary treasurer. He has an intimate knowledge of many aspects of the bibliography of Isaac Newton, in particular of his manuscripts, and it has been arranged that after his retirement his services shall still be available to the Society, to assist Prof. H. W. Turnbull in editing the Newton letters. It is to be hoped that for many years to come Mr. Robinson's familiar figure will be seen about the Royal Society Library, working among the manuscripts that he loves so well.

Reports on German War-time Industry and Science

Reports of war-time scientific and industrial activities in Germany have been available to interested parties for some time. These reports were prepared by B.I.O.S. (British Intelligence Objectives Sub-Committee), its American counterpart, F.I.A.T. (Field Information Agency, Technical), and the combined Anglo-American Agency, C.I.O.S. (Combined Intelligence Objectives Sub-Committee) which preceded them. Actual investigations in Germany ceased at the end of June 1947. To date, 2,720 reports have been issued. It is stated that more than one million copies have been sold or distributed to the universities, learned societies, trade and research associations and principal public libraries of Britain. The Board of Trade has now arranged for experts in each of the major fields to prepare critical summaries suitable for publication. These reports will be known as "B.I.O.S. Overall Reports" and there will be fifty of them, all of which are expected to be printed by the end of June. The first, on the petroleum and synthetic oil industry of Germany, has been published; the next six reports will be on shipbuilding and marine engineering, the German timber industry, the glass industry, the German road system, agriculture, and the rubber industry. All inquiries about these reports should be addressed directly to the Board of Trade, T.I.D.U., Research Section, 40 Cadogan Square, London, S.W.1.

The Foreign Office announces the publication and distribution of the first volumes of the "FIAT Review of German Science", compiled by German experts under the direction of the British, American and French Field Intelligence Agencies (Technical). The Review is written in German and covers fundamental research in pure science during the years 1939–46. By agreement between the British, American and French agencies, the first printing is a restricted edition for official distribution between the three Allies and U.N.E.S.C.O. The British share of about 250 sets will be issued to Government and other bodies within the Commonwealth, to universities and medical schools and to the libraries of certain learned and professional societies. It is hoped that the edition will be completed within the next six months. The Allied edition of the FIAT Review will be followed by a German edition. The latter, also printed in German, will be published by Dieterich'sche Verlagsbuchhandlung, Wiesbaden, Germany, and will be obtainable through normal trade channels. It is understood that volumes will not be sold separately but only in sets comprising the titles under the headings physics, chemistry, mathematics, medicine, biology and sciences of the earth.

Eclipse Observations for Geodesy

It is now possible to amplify the brief reference in *Nature* of February 7 (p. 196) to the application to geodesy of the times of contact to be observed at different stations on the track of the annular eclipse of May 8–9, 1948. The first suggestion that such observations might provide information as to the earth's shape over areas where geodetic triangulation is impracticable was made by Mr. G. E. Barton (*Mon. Not. Roy. Ast. Soc.*, **64**, 105; 1926). His observations at Benkoelen at the eclipse of January 14, 1926, were spoilt by an unfortunate accident, but the idea was afterwards adopted, and expeditions from a number of countries used improved methods of time determination of such observations at the total eclipses of 1945 and 1947 by parties well separated in longitude. For the annular eclipse of next May, the National Geographic Society of the United States has prepared an elaborate scheme of observations at seven ground stations from Mergui in southern Burma to Kiska in the Aleutians. These will be supplemented by observations from aeroplanes of the U.S. Air Force; photographs of the eclipse will be taken from above the clouds from positions determined by short-range radar navigational methods.

The U.S. Army's Map Service, Engineer and Signal Corps, the U.S. Navy, Air Force, Bureau of Standards, Coast and Geodetic Survey and State Department will co-operate with the National Geographic Society in the scheme. The leaders of the different parties are to be as follows: at Mergin, Mr. E. A. Halbach; at Bangkok, Prof. Charles H. Smiley with Prof. C. W. Miller; at Wu-K'ang, China, Father Francis J. Heyden with Dr. V. C. Chang; at Cho-nan, Korea, Dr. George van Biesbroeck; at Kiska and Adak, Lieut.-Cmdr. Clarence R. Reed and Mr. Clarence A. Shelton; while at the Japanese island of Rebun Jima there will be a Japanese astronomer selected by Prof. Hagihara, of the Tokyo Observatory. This marks a welcome move towards international co-operation in science between Japan and the United States. Measurements of the times of contact will be made by photographing the eclipse on 35-mm. sound motion pictures which will record the ticks of a chronometer on the sound track. The chronometers will be checked and rated from radio time-signals. The techniques which make these observations practicable have been developed to a high degree of efficiency in the last twelve years.

Journal of the Institute of Navigation

The recently founded Institute of Navigation, the headquarters of which for the present are at the Royal Geographical Society, Kensington Gore, London, S.W.7, has issued the first number of its quarterly *Journal* (London: J. Murray. 25*s*. per annum). The object of the Institute is to unite those interested in the science and art of navigation, both by sea and in the air. Fellows are those who are either professional navigators or who have made outstanding contributions to the science of navigation; members are those who are generally interested. The Astronomer Royal is president of the Institute, and he has contributed to the new *Journal* an introductory address on the development of navigation. Other articles are on radio aids to navigation, consol, pressure pattern flying and many other topics. The new ocean weather service also finds a place: its ships, equipment and tasks are explained. The *Journal* promises to be a useful addition to the list of scientific periodicals.

Plant Disease Charts

Plant Protection, Ltd., has recently issued two useful wall charts illustrating common and important crop diseases and pests. Both charts are beautifully produced in colour, depicting parts of the plants diseased and the insects where such are concerned. One is entitled "Some Crop Pests and Diseases" and illustrates and describes the following: tomato blight, celery leaf-spot, celery leaf miner, cabbage white caterpillar, black aphis, potato blight, carrot fly, turnip flea beetle, onion mildew, chocolate spot of broad bean, mole cricket, locust, pea and bean weevil, leatherjacket, wireworm, cutworm. The other, "Pests and Diseases of Apples", deals with brown rot, woolly aphis, sucker, apple and pear scab, winter and March moths, sawfly, capsid bug, codling moth, apple blossom weevil and apple mildew. Methods of prevention or protection are shortly described in each case. These wall charts will be a valuable visual aid for schools and agricultural colleges and institutes, which can obtain copies free of charge from Plant Protection, Ltd., Yalding, Kent.

Biology of Lice

A second edition of the booklet entitled "Lice" by Dr. John Smart, published as Economic Series No. 2A by the British Museum (Natural History) has recently appeared (British Museum (Natural History), London, S.W.7, 1948. 9*d*.). It deals with the incidence, development and habits of lice affecting man and the best methods for controlling these pests. During the six years interval that has elapsed since the appearance of the first edition of this booklet, much new knowledge concerning lice has come to hand, especially relative to control measures acquired during the War. Information on these and other features are incorporated in the new edition.

International Conference on the Physics of Metals

The Netherlands Physical Society is organising an international conference on the physics of metals, to be held at Amsterdam during July 12–18, after the Assembly of the International Union of Pure and Applied Physics. The provisional programme includes general lectures by Dr. R. Kronig (Delft) on the electronic structure of metals; Prof. L. Pauling (Pasadena) on valency in metals; Dr. H. B. G. Casimir (Eindhoven) or Prof. C. J. Gorter (Leyden) on superconductivity; Sir Lawrence Bragg (Cambridge) on slip in metals; Prof. N. F. Mott (Bristol) on work hardening and creep in metals; H. Borelius (Stockholm) on transitions in super-cooled metallic solutions; A. Guinier (Paris) on precipitations in metals; Prof. W. G. Burgers (Delft) on crystal growth; Prof. J. H. van Vleck (Harvard) on fundamentals of ferromagnetism. The reception committee in Amsterdam is prepared to give advice and to make hotel reservations. Particulars of the conference can be obtained from Prof. C. J. Gorter, Kamerlingh Onnes Lab., Nieuwsteeg 18, Leyden.

Summer School in Chemistry at Dublin

A SUMMER SCHOOL IN CHEMISTRY is being arranged by the Irish Chemical Association and will be held in the Department of Chemistry, University College, Dublin, during July 5–9. Four courses of lectures will be given: "Some Recent Advances in Chemotherapy", by Dr. V. C. Barry, of the Medical Research Council of Ireland; "Recent Advances in the Determination of the Structure of Organic Compounds", by Prof. W. Cocker, professor of chemistry, Trinity College, Dublin; "Recent Advances in Biochemistry", by Prof. E. J. Conway, professor of biochemistry and pharmacology, University College, Dublin; "The Electronic Theory in Chemistry", by Prof. T. S. Wheeler, professor of chemistry, University College, Dublin. Particulars of the School can be obtained from the honorary secretary, Irish Chemical Association, The Laboratory, 12 Dawson Street, Dublin, to whom applications to attend must be sent not later than June 26.

British National Committee for Crystallography

THE Royal Society, as the national body adhering to the newly formed International Union of Crystallography, has recently set up a British National Committee for Crystallography under the chairmanship of Sir Lawrence Bragg. The members of the Committee are: Prof. W. T. Astbury, Prof. J. D. Bernal, Mrs. D. C. Hodgkin, Mrs. K. Lonsdale, Sir George Thomson, Prof. C. E. Tilley (all representing the Royal Society), Dr. G. M. Bennett (Chemical Society), Mr. D. A. Oliver (Institute of Metals), Prof. E. G. Cox (Institute of Physics), Dr. C. Sykes (Iron and Steel Institute), Dr. F. A. Bannister (Mineralogical Society), and Dr. H. Wilman (Physical Society). In addition to the above, Prof. P. P. Ewald, Dr. R. C. Evans and Dr. W. H. Taylor as members of the provisional executive committee of the International Union are *ex officio* members of the National Committee. The first General Assembly of the International Union of Crystallography is being held at Harvard University during July 28–August 3.

Royal Society of Edinburgh: New Fellows

THE following have been elected fellows of the Royal Society of Edinburgh: Sir Robert Allan, 41 N. Castle Street, Edinburgh 2; Prof. J. F. Allen, Department of Natural Philosophy, University of St. Andrews; Mr. Alexander Cullen, architect and town planning consultant; Dr. F. J. Elliott, head of the Department of Physiology, Royal (Dick) Veterinary College, Edinburgh; Dr. M. A. Ellison, principal scientific officer, Royal Observatory, Edinburgh; Major M. D. W. Elphinstone, Threeways, Highfield Road, Chislehurst, Kent; Prof. T. H. Fraser, Department of Economics, Fouad I University, Cairo; Sir John Fryer, secretary of the Agricultural Research Council; Prof. T. N. George, Department of Geology, University of Glasgow; Dr. John Morrison Hay, deputy director and head of Engineering Division, Scottish Seaweed Research Association; Dr. J. F. Heggie, senior pathologist, North Middlesex County Hospital; Dr. G. O. T. D. Henderson, officer-in-charge, Oceanographic Laboratory, Leith; Dr. I. G. W. Hill, lecturer in pharmacology, University of Edinburgh; Dr. W. C. O. Hill, lecturer in physical anthropology, University of Edinburgh; Prof. E. L. Hirst, Department of Organic Chemistry, University of Edinburgh; Mr. E. P. Hudson, director, Scottish Agricultural Industries, Ltd., Leith; Prof. W. Q. Kennedy, Department of Geology, University of Leeds; Mr. J. Gibson Kerr, 51 Castle Street, Edinburgh 2; Dr. D. N. Lawley, lecturer in statistics, University of Edinburgh; Dr. T. N. MacGregor, lecturer in gynæcological endocrinology, University of Edinburgh; Dr. A. P. Orr, deputy director (senior principal scientific officer), Millport Laboratory, Scottish Marine Biological Association; Dr. R. Passmore, lecturer in clinical and industrial physiology, Department of Public Health and Social Medicine, University of Edinburgh; Dr. T. R. Tannahill, lecturer in astronomy, University of Glasgow; Dr. S. I. Tomkeieff, lecturer in geology, King's College (University of Durham), Newcastle-upon-Tyne; Prof. C. H. Waddington, Department of Animal Genetics, University of Edinburgh, director of the Genetics Laboratory of the Animal Breeding and Genetics Research Organisation of the Agricultural Research Council.

Announcements

THE James Tait Black Memorial Prize of the University of Edinburgh for 1947, awarded for a biography or work of that character, has been awarded to Dr. C. E. Raven, regius professor of divinity in the University of Cambridge, and master of Christ's College, for his book "English Naturalists from Neckham to Ray" (see this issue of *Nature*, p. 373).

DR. J. E. KEYSTON, formerly assistant director of scientific research, Admiralty, has been awarded the United States Medal of Freedom with Bronze Palm for promoting interchange of scientific and engineering information and collaborating with American research groups during the Second World War. The investiture took place in Salisbury, Southern Rhodesia. Dr. Keyston has recently been appointed research secretary of the Central African Council (see *Nature*, February 14, p. 230).

THE Committee of Privy Council for Medical Research has appointed Prof. H. P. Himsworth, professor of medicine in the University of London, to be a member of the Medical Research Council.

THE Council of the Royal Statistical Society offers the Frances Wood Memorial Prize, value £30, for competition in 1948. The Prize is offered for the best investigation, on statistical lines, of any problem bearing directly or indirectly upon the economic or social conditions of the people. Essays (which must be either printed or typed, and accompanied by copies of all statistical tabulations and diagrams) must be sent to the honorary secretaries of the Royal Statistical Society, 4 Portugal Street, W.C.2, not later than December 31, 1948.

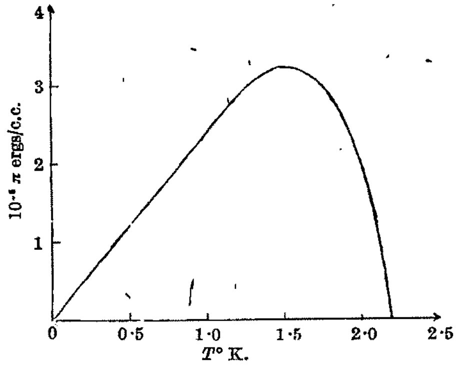
Liquid Helium II

THE classical theory of liquids[1,2,3], of which a general explanation was given by Prof. Max Born and me in a previous article[4], and the quantization of the theory[5,6] which followed, led to a conception of the nature of viscosity and thermal conduction in liquids which we hoped would contribute towards the understanding not only of normal liquids, but also of 'quantum liquids', of which helium II and the electrons in superconducting metals are known examples.

The detailed application of these results to helium II has now been completed, and it has been found possible, without further assumption, to explain all the well-known properties of this liquid. The essential feature of a quantum liquid, as we observed previously[6], is the distinction between the intensive properties defined thermodynamically and from the point of view of kinetic theory. Of special importance is the distinction between the 'thermodynamic' pressure p, defined in terms of the work done pdV during the displacement of a surface in the liquid, and the 'kinetic' pressure p_1, the gradient of which determines the mean motion of the molecules. It can be shown that the difference π between these two quantities first becomes numerically significant just below the λ-point; it is represented as a function of temperature in the accompanying figure.



π AS A FUNCTION OF TEMPERATURE AT THE SATURATION VAPOUR PRESSURE

The equation of motion of the quantum liquid is

$$\rho\frac{du}{dt} + \frac{\partial p}{\partial x} = -\frac{\partial \pi}{\partial x}, \qquad (1)$$

where ρ is the density and u the macroscopic velocity. It follows rigorously that a reformulation of the first law of thermodynamics is required below the λ-point, of such a kind that it reduces to the usual law

$$dQ = dU + pdV \qquad (2)$$

for the ideal quasi-static process, but has quite a different form

$$dQ = d(U - \pi V) + p_1 dV \qquad (3)$$

for steady motion, such as is observed in the transfer effect (studied in detail by Daunt and Mendelssohn[7]), and yet another form

$$dQ = d(U + \pi V_0 - \pi V) + p_1 dV \qquad (4)$$

for wave motion, V_0 being the rest volume of the liquid. The anomalous specific heat and density of helium II is thus explained by the presence of thermal waves. Similar waves have been observed in ordinary liquids[8], but are strongly damped and have only a small group velocity.

A thermal wave transfers heat energy and the liquid bulk in opposite directions in a ratio depending only on the temperature. Kapitza's experiments[9] on the thermomechanical effect in a narrow slit have a quantitative explanation not, as Landau[10] suggests, in the motion of a superfluid at absolute zero, but in the almost isothermal passage of a thermal wave through the slit. Peshkov's observations[11] of temperature waves in helium II also have a quantitative explanation in terms of the thermal waves.

Earlier theories due to F. London[12,13] and Tisza[14,15] suggest that superfluidity is connected with the condensation which occurs in a Bose gas not far from the λ-point. A serious objection to these theories is the occurrence of entirely analogous phenomena in superconductors, where the electrons obey Fermi statistics. The quantum theory of liquids is, however, equally applicable to superconductivity, and an interesting feature of the theory outlined here is that it can explain also phenomena in superconductors: one requires only to replace the mechanical pressure by the electromagnetic stress tensor and to represent the almost stationary metallic ions by a conservative field of force.

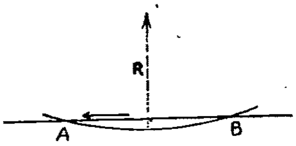
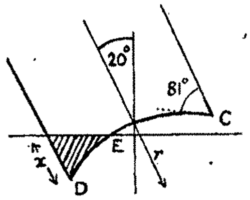
Theory of Skating

IT is perhaps less common than it was to find the phenomenon of regelation put forward as a complete explanation of skating. Very probably anyone with a scientific education will suspect that plastic flow in the solid ice plays an important part, and the following observations will, if they are accepted, serve to strengthen that opinion.

It is clear at once that regelation as ordinarily understood in this case must require a rapid flow of heat through the skate blade from back to front, and yet the temperature gradient must be an infinitesimal one. Obviously the effect of friction must also be included, and since the publication of Bowden and Hughes' paper[1] in 1939 it has become possible to calculate what this may be. What no one seems to know with any accuracy is the depth of penetration of the skate blade and the amount of ice actually displaced. This is not easy to determine experimentally, and for present purposes the results have been calculated from simple observations using a skate ground to accurately known dimensions. Skates are usually ground to a form decided more or less empirically, the radius of curvature of the blade not being constant along the length. It is therefore important to record that a skate of uniform vertical radius (R) 72 in. and transverse radius (r) 0·5 in. performs admirably and possesses, indeed, some superiority over the ordinary run[2]. The blade has a thickness of 5/32 in. and the angle between the side of the skate and the bottom edge is accordingly 81°. In the calculations, this skate is considered at an angle of 20° to the vertical and is supposed to carry a load of 10 stones weight.





The depth of penetration of the blade is clearly a question which depends on the pressures concerned: the skate will sink in until the area in contact is such that the pressure is insufficient for further sinking. Curiously enough, this matter turns out to be less uncertain than might be expected. Double lines such as would be (and are) formed when the edge C comes in contact with the ice are always avoided in competitions, and the fact that they can be avoided at angles of about 20° (got from photographs) shows that the penetration must have an upper limit which with this particular skate is about 1/32 in. From this it follows that 0·0018 c. in. (or 0·03 gm.) of ice are displaced per length AB: the chord AB being in this case 4·38 in. The heat required to melt this ice is then 2·4 cal.

Friction can account for very little of this. From the equation

$$Q = \frac{Mg\mu_k}{J}L,$$

where M is load and L is AB, we find (using Bowden and Hughes' value for μ_k for *brass* on ice) only 0·363 cal. per length AB (AB = 4·38 in.). The ice melted would therefore be only 0·0045 gm.—about one eighth of the amount estimated to be displaced.

To estimate the regelation effect without reference to the difficulty about heat flow, we may find how deep the skate would sink under the stated load if there is a temperature gradient in the ice of the sort existing in rinks. 10° C. per in. is here quite a common gradient; out of doors the conditions are, of course, very variable; but a surface temperature of 0° C. seems to be the best for skating, and at low temperatures when there is a hard frost skating is more difficult.

The freezing-point lowering being given by

$$t = 0{\cdot}0072\,P,$$

where P is the pressure in atmospheres, it remains to find the area in contact with the ice at a penetration of 1/32 in. The arc DE having a value of 0·0744 in. when $x = 0{\cdot}0313$ in., the area is approximately given by 2·2 (0·0313 + 0·0744), which comes to 0·233 sq. in. From this the freezing point comes out at about − 0·3° C.—or a depth of 0·03 in. below the surface, which is of the correct order.

Nevertheless, this static picture will not do. At 10 m.p.h., heat would have to flow from B to A at some 100 cal. per sec.: an impossible rate having regard to the conductivity of steel, the cross-section area and the temperature difference of only a fraction of a degree centigrade. It looks very much more likely that the skate makes its track in the ice through plastic deformation of the solid rather than that melting plays any great part. The pressures applied to the ice by a moving skate must be of the order of some thousand pounds per square inch, and under such a stress the ice would give way. It is of interest, however, in regard to the question of friction, to note that Bowden and Hughes state that the lowest coefficients of kinetic friction were obtained when a water film of the order of 7×10^{-3} cm. thickness is present. The water formed by friction in the present case would allow of a layer of some 5×10^{-3} cm. thickness, and this might be sufficient for lubrication.

Chromatic Aberration of Electrostatic Lenses

The focal length of a three-aperture electrostatic lens follows from the general paraxial ray equation:

$$4\Phi r'' + 2\Phi' r' + \Phi'' r = 0,$$

where Φ is the potential along the axis ($r = 0$), and Φ_0 is the acceleration voltage.

When the potentials of cathode and intermediate electrode are equal, the chromatic aberration due to $\Delta\Phi_0/\Phi_0$ is zero according to this equation (although Φ_0 must be kept constant within 1 per cent to reduce the influence of external fields of transformers, etc.).

This is not so, however, when the relativity correction is taken into account.

The focal length is influenced by applying an extra constant voltage e between cathode and intermediate electrode. Chromatic aberration is caused by this extra voltage. It has proved possible to compensate the relativity aberration by this second chromatic aberration due to $\Delta\Phi_0/\Phi_0$ by choosing a suitable value of e/Φ_0. So every acceleration voltage determines its specific value of e/Φ_0.

When cathode and intermediate electrode potential of a certain weak electrostatic lens are equal ($e = 0$), the aberration due to relativity correction at 100 kV. is

$$\frac{\Delta A}{A} = -0{\cdot}14\,\frac{\Delta\Phi_0}{\Phi_0}, \qquad (1)$$

$1/A$ being the focal length.

Using a specific value of e/Φ_0 to eliminate this aberration, the constancy of e is determined by the chromatic aberration due to $\Delta e/e$.

$$\frac{\Delta A}{A} = -0{\cdot}16\,\frac{\Delta e}{e}. \qquad (2)$$

The advantage over the $e = 0$ type lenses follows from equations 1 and 2.

As the intermediate electrode is taking no current, stabilization of e causes no difficulties. The difficulty in stabilizing Φ_0 is that emission current is being taken. The advantage over magnetic lenses is clear, chromatic aberration of this type being

$$\frac{\Delta A}{A} = C.\ \frac{\Delta \Phi_0}{\Phi_0},$$

where C is about 0·8.

Absorption Band Spectrum of S_2 in the Schumann Region

WHILE the main band-systems of the molecules O_2, S_2, Se_2 and Te_2 of the sixth periodic group have been the subject of numerous publications, there is little known about the systems of these molecules lying in the far ultra-violet. In all cases such systems have been found in absorption, but they have been analysed only partially for their complex structure. The absorption bands of Te_2 and Se_2 between 2500 and 1950 A. and 1950 and 1750 A. respectively have been photographed by Choong Shin-Piaw[1]. His analysis is incomplete and violates the empirical rule of Mecke–Birge. Choong Shin-Piaw believed all the molecules Te_2, Se_2 and S_2 to show the same peculiarity, and referred to the results published by Wieland, Wehrli and Miescher[2] on S_2. Yet these authors emphasized the provisional character of their interpretation.

We have therefore reinvestigated the S_2-bands between 1600 and 1900 A. by means of a 1-metre vacuum grating spectrograph (dispersion 8 A. per mm.). The continuum was furnished by a Lyman explosive discharge through a quartz capillary. Within the accuracy of measurement, which for most of the sharp bands is better than ± 1 cm.$^{-1}$, all the recorded bands can be arranged in two systems which we will call C and D.

The bands of system C are degraded towards shorter wave-lengths and appear to have several heads up to six, the intensity of which depends strongly from the vibrational quantum number v'. By arranging the strongest head of each band in a scheme, one gets for the wave-numbers of the heads the expression :

$$\nu = 55598{\cdot}2 + 830{\cdot}2\ (v' + \tfrac{1}{2}) - 3{\cdot}75\ (v' + \tfrac{1}{2})^2 - 725{\cdot}1\ (v'' + \tfrac{1}{2}) + 2{\cdot}85\ (v'' + \tfrac{1}{2})^2.$$

The system thus consists chiefly of the two vibrational progressions $v' = 0$ and $v'' = 0$. The vibrational constants of the lower level are in good agreement with the data of the ground-state of S_2 given by Olsson[3] ($\omega_e'' = 725{\cdot}8$, $\omega_e''x_e'' = 2{\cdot}85$). The high intensity of the bands points to a transition between states of like multiplicity. The ground-state being $^3\Sigma_g^-$, the upper state might then be of the $^3\Sigma_u^-$ or $^3\Pi_u$ type. Considering the number of heads and the multiplet separation, which is larger than in the ground-state, $^3\Pi_u$ is perhaps more probable.

System D, situated at shorter wave-lengths, is about of equal intensity, but its aspect is more complex. There are apparently three groups of bands (a, b, c in the accompanying [illegible]ion) which are observed several time[illegible]s formed by three strong heads. Th[illegible]ing arranged in a scheme, the vibrational [illegible]s turn out to be nearly the same for all t[illegible]s. From the strongest heads on the mor[illegible]angible side of each group, the following [illegible]ants are derived :

Group [illegible]			Group b			Group c		
ν_e	=	58515·1	ν_e	=	58707·2	ν_e	=	58976·8
ω_e'	=	794·2	ω_e'	=	793·8	ω_e'	=	793·7
$\omega_e'x_e'$	=	4·00	$\omega_e'x_e'$	=	4·00	$\omega_e'x_e'$	=	4·00
ω_e''	=	724·4	ω_e''	=	724·6	ω_e''	=	725·1
$\omega_e''x_e''$	=	2·85	$\omega_e''x_e''$	=	2·85	$\omega_e''x_e''$	=	2·85

Here again the lower level is identical with the ground-state of S_2. As an arrangement of the groups or systems in series of electronic states does not seem possible, no traces of higher series members being recorded, the three groups must be regarded as belonging to one and the same system showing atom-like separations. This analysis of system D departs from the one given earlier. The bands being shaded towards the violet, the vibrational frequency of the lower level is expected to be smaller than that of the upper one. This is actually the case.

The details of this investigation and a fuller discussion of the results will be given in a later paper to appear in the *Helv. Phys. Acta*.

Energy of the Ground-State of Helium-like Atoms

THE purpose of the present note is to suggest that the discrepancy between the measurements of helium-like spectra made by F. Tyrén and by H. Flemberg[1], on one hand, and the theoretical calculations made by E. Hylleraas (non-relativistic) and by me[2] (relativistic corrections), on the other hand, may possibly be due to the same reason which causes the discrepancy between theory (Dirac's fine-structure formula) and experiment (Lamb and Retherford[3]) in the hydrogenium spectrum.

The possibility of removing this latter discrepancy by taking into account the interaction of the electron with the radiation field has been the subject of discussions at a conference on Shelter Island this year[4], and has inspired calculations by Weisskopf[5] and by Bethe[4].

According to Bethe's calculations, the shift of an *ns* level should become $W' \sim kZ^4/n^3$ cm.$^{-1}$, where the factor k is about 0·26 for $Z = 1$ and $n = 2$ and does not change very rapidly with Z and n. This agrees well with the observed level-shift.

This result can be applied to the ionization energy of helium-like atoms if as a first rough approximation the interaction between the two electrons is neglected. In the accompanying table I have calculated the ratio W'/Z^4, where W' is the difference between the calculated and the experimental ionization energy.

Z	W'	W'/Z^4
2	+ 14	0·88
3	+ 13	0·16
4	+ 84	0·33
5	+ 195	0·31
6	+ 311	0·24
7	+ 537	0·22
8	+ 1080	0·26
9	+ 1844	0·28
12	+ 4861	0·23
13	+ 4966	0·18

The value 0·88 obtained for $Z = 2$ is, of course, very uncertain, since the theoretical value lies within the experimental limits of error.

Theory of the Anomalous Skin Effect in Metals

Pippard[1] has recently made an experimental and theoretical study of the skin effect in metals at high frequencies, in which he showed that the usual theory of the effect is no longer valid at low temperatures owing to the breakdown of Ohm's law when the free path of the conduction electrons becomes comparable with the penetration depth of the electric field. With the aim of putting Pippard's provisional theory of the anomalous effects on a more rigorous basis, we have reformulated his equations using the methods of the modern electron theory of metals, and we have succeeded in obtaining explicit solutions which make it possible to give a quantitative account of the phenomena to be expected over the whole frequency- and temperature-range.

We consider a semi-infinite metal and assume the electrons to be quasi-free, the energy being proportional to the square of the wave-vector. The relation between the current density and the (unknown) electric field at any point in the metal, for arbitrary values of the frequency ω and the free path l, can then be obtained by the usual statistical methods of the theory of metals based on the Boltzmann equation[2]. On combining this relation with Maxwell's equations, we obtain the following integro-differential equation for the electric field $f(x)$:

$$f''(x) = i\alpha \left\{ p \int_{-\infty}^{\infty} k(x-y)\, f(y)dy + (1-p) \int_{0}^{\infty} k(x-y)\, f(y)dy \right\}, \qquad (1)$$

where

$$k(u) = \int_{1}^{\infty} \left(\frac{1}{s} - \frac{1}{s^3}\right) \exp\{-s(1+i\omega\tau)|u|\}ds,$$

x is the distance into the metal measured in units of l, $\alpha = 3l^2/2\delta^2$ (δ being the classical skin-depth), τ is the time of relaxation of the electrons, and it has been assumed that a fraction p of the electrons is scattered specularly at the surface of the metal while the rest are scattered diffusely. Also, $f(x)$ is to be an even function of x. The basic equation of Pippard's treatment (*loc. cit.*, equation (7)) may be written in a form which differs only in minor detail from equation (1).

Equation (1) has been solved for the two limiting cases $p = 1$ and $p = 0$ by means of the theory of Fourier integrals[3]. The electric field is, in general, a very complicated function of x, but for comparison with experiment it is not necessary to know $f(x)$ explicitly since all observable quantities can be expressed in terms of the surface impedance Z, defined as $4\pi/c$ times the ratio of the electric to the magnetic field strength at the surface of the metal. For $p = 1$ we find that

$$Z = \frac{4\pi\omega l}{ic^2}\,\frac{f(0)}{f'(0)} = \frac{8i\omega l}{c^2(1+i\omega\tau)} \int_0^{\infty} \frac{dt}{t^2 + \dfrac{i\alpha}{(1+i\omega\tau)^3}\varkappa(t)}, \qquad (2)$$

where

$$\varkappa(t) = \frac{2}{t^3}\{(1+t^2)\tan^{-1} t - t\}.$$

The expression for $p = 0$ is more complicated, but the results differ only in detail from those obtained for $p = 1$.

For frequencies which are not too high, we have $\omega\tau \ll 1$, and the integral in (2) is then a function of the single parameter α. In this case equation (2) reduces to the classical expression $Z_{cl} = (\pi\omega l/c^2)\sqrt{(6/\alpha)}\,(1+i)$ when $\alpha \ll 1$, and to

$$Z_\infty = \frac{8\pi^{2/3}\omega l}{3\sqrt{3}\,.\,c^2\alpha^{1/3}}\,(1+\sqrt{3}\,i) \qquad (3)$$

when $\alpha \gg 1$. (For $p = 0$, Z_∞ has 9/8 times the value (3).) For intermediate values of α, Z has been obtained by numerical evaluation of the integral in (2). From the definition of α, it follows that α is proportional to l^3 for a given metal and a given frequency. Hence Z varies as $l^{-1/2}$ in the classical case but is independent of l when $\alpha \gg 1$. This result is in agreement with Pippard's observations of the resistive part of Z at a wave-length of 25 cm., and represents the quantitative refinement of his theoretical interpretation in terms of an 'ineffectiveness concept'[1]. From a detailed comparison of the experimental and theoretical curves, it is possible to estimate the value of α and hence of the free path corresponding to any particular temperature. Thus for Pippard's mercury specimen we find that $\alpha = 1{,}550$ and $l = 8{\cdot}5 \times 10^{-4}$ cm. at $T = 3{\cdot}72°$ K.

Writing $Z = R + iX$, we have $R = X$ in the classical limit, while equation (3) shows that

$R = X/\sqrt{3}$ when $\alpha \gg 1$. X has not been measured directly, but Pippard[4] has obtained some indirect experimental evidence which indicates that X does, in fact, exceed R in the anomalous region.

The expression (2) has further been computed as a function of $\omega\tau$ for several values of the ratio $\alpha/\omega\tau$. ($\alpha/\omega\tau$ is independent of ω and, for a given metal, determines the value of l; the values chosen correspond to several temperatures between room temperature and liquid helium temperatures.) The ratios R/R_{cl} and X/X_{cl} are found to have the classical value unity for sufficiently low, and again for sufficiently high, frequencies (which are, however, well below the frequency for which the metal becomes transparent), and to pass through a maximum value at intermediate frequencies. The anomalous effects become less marked as the temperature increases, and have disappeared almost completely at room temperature. To give some idea of the orders of magnitude involved, choosing values of the parameters which correspond to a very pure specimen of silver at liquid helium temperatures, we find that R/R_{cl} attains a maximum value of 180 at a wave-length of 69 μ, while X/X_{cl} attains a maximum value of 5·3 at a wave-length of 7·6 cm. The absorption coefficient of the metal is increased in the same ratio as R; thus in the above example the theoretical absorption coefficient at 69 μ is $1{\cdot}44 \times 10^{-3}$, whereas the classical value is only 8×10^{-6}. Since the absorption is so small even in the anomalous case, an experimental verification of these predictions is likely to be very difficult.

A full account of the theory is to be published elsewhere.

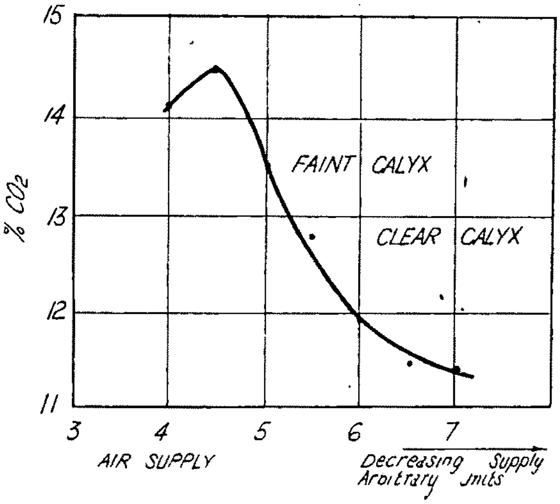
Use of 'Calyx' Burner to Determine Combustion Conditions

Brinsley and Stephens[1] have described an apparatus in which air and gas are pre-mixed and burned in a vessel from which the only exit is a small hole. When the proportion of air in a mixture originally air-rich is gradually reduced, the flame alters, and at one stage a violet sheath appears, surrounding the lower part of the flame. This sheath Brinsley and Stephens call a 'calyx'; they claim that it appears when the gas–air is that theoretically required for complete combustion.

It was thought that sampling the products of combustion as the theoretical mixture was burning would enable the maximum possible concentration of carbon dioxide in these products to be determined by a single analysis. This would be of service in testing gas appliances.

A mixture of coal gas and air was used. It was found that the flame is stable over only a small range of needle-valve settings: both the rate of supply of the mixture and its constitution have to be approximately correct or the flame goes out. Adjustment is not difficult once the operator has become familiar with the appearance of the flame in various circumstances, and the flame changes described by Brinsley and Stephens can then be readily observed.



Tests were made keeping the gas supply constant and cutting down the air in a series of arbitrary steps; at each setting a sample of the combustion products was taken and analysed for carbon dioxide. The results are shown in the accompanying graph. It will be seen that the calyx did not appear until after the maximum carbon dioxide concentration had been passed, and even then was only faintly visible. This reveals the chief objection to the use of the phenomenon for determination of theoretical combustion conditions. The calyx does not appear sufficiently suddenly; it 'fades in' as the air supply decreases, and the threshold visibility depends on the eyesight of the observer and on his experience. If it were used for determination of the maximum concentration of carbon dioxide in the combustion products, low results would be very probable.

A New Sulpha Compound ("6257") and its Use in Human Cholera Infection

It was observed by one of us (S. S. B.) in 1939 that hexa-methylene-tetra-amine, in a 10 per cent solution in normal saline, killed cholera vibrio in less than half an hour up to a concentration of 10^{12}. Although interrupted by conditions of field service, efforts resulted in the production of three crude compounds of hexamine linkage to *para*-aminobenzene sulphonamide, experiments with which, on animal and human cholera infection, gave hope of successful chemotherapy against Asiatic cholera. A chance discussion with the scientific department of C.I.B.A. (Basle) resulted in our obtaining a condensation product—"6257"—of two molecules of 2 *p*-amino-benzene sulphonamido-thiazole ('Cibazol') and three molecules of formaldehyde with the formula $C_{21}H_{22}O_6N_6S_4$ (the actual constitution not having yet been worked out) and molar weight much greater than that of any other sulpha compound so far employed in clinical therapy.

In vitro, the bactericidal action of this compound on cholera vibrio was found to be powerful. When one million organisms of either the strain Inaba or Ogawa were seeded into 10 ml. of peptone water (*p*H 8·0) and 50 mgm. of the drug added, suspended in gum arabic in 0·1 ml. volume, it was found that samples plated on alkaline agar, 6, 12 and 24 hours after incubation at 37° C., remained sterile. Further confirmation of this observation was obtained (*a*) by testing the total inoculum of 10 ml. by the pour-plate method, when there was complete absence of growth; and (*b*) by transferring the total inoculum, in portions of 0·1 ml. each, to a hundred tubes of glucose peptone water with Andrade indicator, the absence of visible growth and of acid fermentation being taken as indices of non-viability.

Where the concentration of the drug was less than 50 mgm. (40, 30, 20 and 10 mgm.) well-marked bacteriostatic action was evident on the initial inoculum of one million bacterial cells, as judged by colony counts and hæmocytometer readings in comparison to control tubes. With 5 mgm. of the drug there was no difference between the control and experimental tube readings.

In vivo experiments on mice further confirmed these results. Twenty mice were employed for each experiment. Separate sets of animals were given 50 mgm. and 40 mgm. of the drug by the intraperitoneal, the subcutaneous and the oral routes, in divided doses, for two days prior to the test dose. This was injected intraperitoneally and was kept in the region of 2 *M.L.D.* to exclude mortality by toxic action alone. The mice were thereafter given two doses of "6257", morning and evening, for four days only, and the mortality-rate was observed for fifteen days. 100 per cent protection was obtained by the intraperitoneal and the subcutaneous routes. By oral feeding, however, only 10 per cent of the animals were saved. Post-mortem examination of dead mice revealed that intraperitoneal cholera infection resulted in septicæmia, the vibrios being isolated from heart blood, liver and spleen. Poor absorption of the drug from the intestinal tract, as judged by low blood concentrations, was therefore responsible for the high mortality in this group.

Field trials were carried out in the Tanjore District of South India, where there were cases of Asiatic cholera in many villages. The patients were treated in their homes without any other medical aid, in co-operation with local health authorities. The great majority of cases were under-nourished women and children with purgation, vomiting, suppression of urine and concomitant symptomatology. A specimen of rice-water stool was obtained initially to establish the diagnosis bacteriologically. The drug was then administered in a dose of 6 gm. followed four hours later by another 4 gm., commonly by mouth; where it was not retained, it was given per rectum. Vomiting was invariably stopped and purgation much reduced within six hours; the flow of urine took place by the ninth hour. The alimentation was barley *kanji* with plenty of water, especially soda-water, wherever available, since it helped to re-establish the function of the kidneys. The total dosage was 28 gm., given as 10 gm. on the first day, two doses of 4 gm. on the second day, and two of 1 gm. each morning and evening every subsequent day for five days. Under this regime, cholera vibrios were absent from the stool on the fifth morning. Administration of the drug to other occupants of the hamlet protected them from becoming infected.

To date 85 cases of bacteriologically established Asiatic cholera in twenty-seven villages have been treated, with a case mortality of 4 per cent in contrast with an average mortality of more than 60 per cent during the past seven years. No toxic manifestations with a maximum dose of 50 gm. have been observed. Besides the curative effect of this simple form of therapy under conditions where the possibility of hospitalization and the availability of medical care is slender, its prophylactic and preventive aspects are emphasized.

Detailed investigations are being published elsewhere.

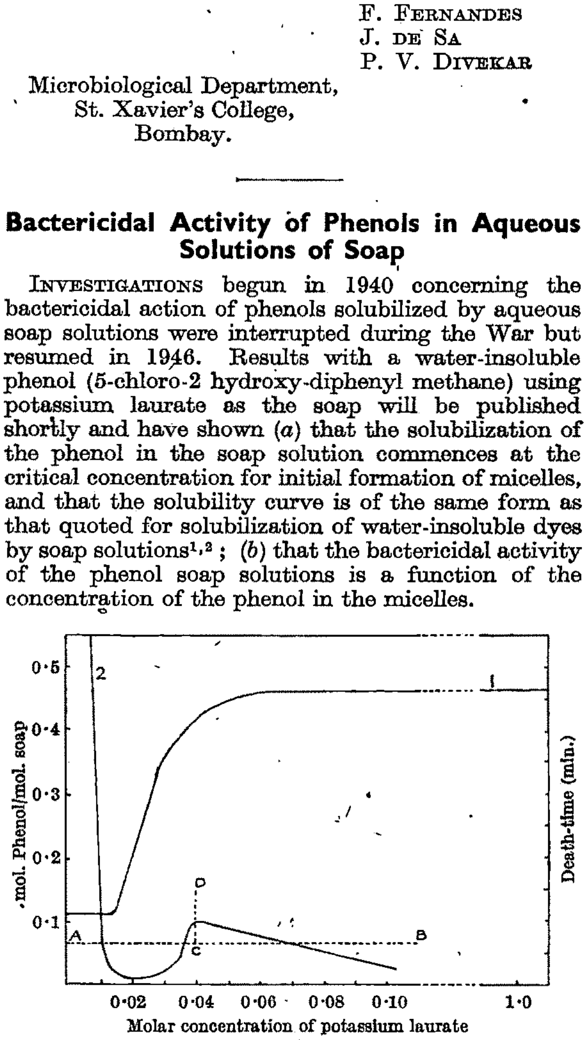
Bactericidal Activity of Phenols in Aqueous Solutions of Soap

INVESTIGATIONS begun in 1940 concerning the bactericidal action of phenols solubilized by aqueous soap solutions were interrupted during the War but resumed in 1946. Results with a water-insoluble phenol (5-chloro-2 hydroxy-diphenyl methane) using potassium laurate as the soap will be published shortly and have shown (*a*) that the solubilization of the phenol in the soap solution commences at the critical concentration for initial formation of micelles, and that the solubility curve is of the same form as that quoted for solubilization of water-insoluble dyes by soap solutions[1,2]; (*b*) that the bactericidal activity of the phenol soap solutions is a function of the concentration of the phenol in the micelles.



Curve 1 in the graph shows the solubility of the phenol in mol. phenol/mol. soap plotted against the molar soap concentration, and superimposed on it is Curve 2 representing the activity, in terms of the death-time of *B. coli*, at points along the line *AB* throughout which the ratio phenol/soap remains constant.

Below 0·01 *M* potassium laurate, the death-time decreases rapidly as the line is traversed in the direction of *B*, the concentration exponent over this range being of the order expected for an aqueous solution of a phenol. At 0·01 *M* potassium laurate the slope of the death-time curve alters sharply, first flattening, then rising to a maximum at about 0·04 *M* potassium laurate and finally decreasing again with concentration. In the range 0·01–0·04 *M* potassium laurate, the amount of the phenol which the soap will solubilize increases rapidly; but as the phenol/soap ratio remains constant in the solutions used; the degree of saturation of the micellar material actually decreases from about 0·015 *M* to 0·04 *M*, and it is this fact that is responsible for the rise of death-time in this range. That activity is greatest at approximately 0·01 *M* soap is due to the concentration of phenol in the micelles being greater at this point than elsewhere along the line *AB*. Death-times along line *CD* decrease rapidly as the amount of phenol per molecule of soap increases, indicating that maximum bactericidal activity is attained where the micelles are fully saturated with the phenol.

Experiments using sparingly soluble phenols like 2-chloro-5 hydroxy-1 : 3-dimethylbenzene and water-soluble phenols such as the cresols are in progress, and results will be published in due course.

Calcium-Deficient Media: Their Effect on Phage Action

While typing staphylococci by the bacteriophage method of Wilson and Atkinson[1], I encountered three batches of nutrient agar that were strongly inhibitory to phage action; several of the phage filtrates had to be used in a concentration one hundred times greater than normal.

Stassano and de Beaufort[2], Asheshov[3], Bordet[4], Burnet[5], and others have reported on the inhibitory effect of sodium citrate when added to media used for the demonstration of phage action. This suggested that a deficiency of calcium in the medium might be responsible for the inhibition of phage action referred to above. On the suggestion of Dr. G. P. Gladstone of the Lister Institute, calcium chloride in concentrations of *M*/100 were added to two of the batches of inhibitory media; the third was unfortunately discarded. The effect was striking. The media were now found to be completely satisfactory for the demonstration of bacteriophage activity.

As a result of this experience, it is considered advisable to add calcium chloride to solid culture media that are to be used for the typing of staphylococci by the bacteriophage method.

Production of Itaconic Acid and Kojic Acid by a Species of *Aspergillus*

The observation reported in the present note relates to an *Aspergillus* with yellow- to ochraceous-coloured conidia. The mould does not appear to correspond entirely with any published description.

Grown upon the surface of a 20–25 per cent sucrose solution containing the nutrient salts of Kardo-Ssyssojewa's medium[1] at 28° C. in the presence of calcium carbonate, this mould produces both itaconic acid and kojic acid. The relative proportions in which the two compounds appear may be varied by varying the conditions of the fermentation. At higher temperatures itaconic acid preponderates and may amount to more than 20 per cent of the weight of the sugar provided.

The itaconic acid was prepared from the calcium salt which is present in solution and often also separates as nodules on the underside of the mould. Its crystals showed characteristic cleavage; m.p. 163–166° C., not altered by admixture with authentic itaconic acid; analysis: C, 46·41, 46·53; H, 4·92, 5·00 per cent (calc. for $C_5H_6O_4$: C, 46·15; H, 4·61 per cent); equivalent, 65; the calcium content of the calcium salt was 21·5 per cent.

The kojic acid was prepared *via* the insoluble copper salt. It melted at 152–153° C.; its solution gave an intense blood-red colour with ferric chloride.

Itaconic acid has hitherto been shown to be produced by *A. itaconicus*[2] and by *A. terreus*[3]. The itaconic acid fermentation by *A. terreus* has since been extensively investigated in the United States in the Fermentation Division of the Northern Regional Research Laboratory[4–7].

The work now reported is being continued, and it is hoped to publish it fully elsewhere in due course.

It is a pleasure to acknowledge the assistance of my colleague Mr. J. H. Morrison and of a former colleague, Mr. C. W. Hutchinson.

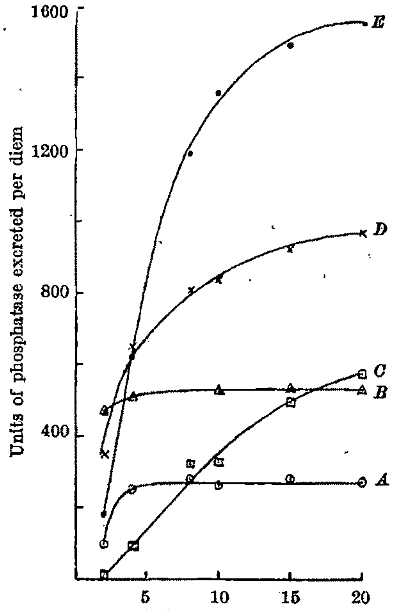
Presence of Substances Inhibitory to Acid Phosphatase in Normal Human Urine

In adult bilateral cryptorchid human subjects, a correlation has been found between androgen excretion in the urine and the amount of acid phosphatase in the semen[1]. The suggestion was made that if a similar correlation was found in normal subjects, measurement of acid phosphatase in semen might suffice for appraisal of urinary androgen content. Since specimens of urine are usually more easily obtained than those of semen, it seemed to be worth while to determine whether a correlation exists between urinary androgens and urinary acid phosphatase.

Recently Burgen[2] has described a method for the estimation of the urinary excretion of acid phosphatase, and his results on normal human subjects were a further indication that some correlation might exist between the daily excretion of this enzyme and that of 17-ketosteroids. It was found that the level of excretion of acid phosphatase is low in male children, but that from puberty onwards there is a sharp increase reaching a maximum in the fourth decade and then falling off in old age. Such a distribution resembles the known distribution of 17-ketosteroids with age in male subjects.

Experiments were therefore undertaken to compare the daily output of urinary acid phosphatase and urinary 17-ketosteroids by normal male subjects. The ketosteroid estimations were carried out by a standard colorimetric procedure and the acid phosphatase measurements were made, at least initially, by the method described by Burgen[2].

Difficulty in the estimation of the enzyme was encountered when some rather concentrated urines (daily volumes less than 700 ml.) were used. In Burgen's procedure the urine is prepared for assay by preliminary dilution with an equal volume of water. In order to reduce the blank values of these concentrated urines, higher dilutions were employed, and it was found that in some cases the amount of enzyme apparently increased with increasing dilution. In some urines the apparent amount of enzyme was still increasing at the limit of dilution in which it was practicable to estimate it. In other urines the amount of enzyme increased to a maximum after slight dilution of the urine, and then maintained a constant value to the limit of measurement. Urine from the same subject showed different behaviour with respect to this dilution effect on different occasions. Representative curves for five different urines are reproduced herewith. The daily output of acid phosphatase as computed from measurements of the enzyme on urine specimens initially diluted from two to twenty-fold is plotted against the dilution employed. It is clear that a reliable estimate of the urinary acid phosphatase can be obtained only on urines that show constant values on dilution (Curves *A* and *B*). In other cases no one value can be taken as a true measure of the enzyme content (Curves *C*, *D*, and *E*).



EFFECT OF DILUTION ON THE APPARENT ACID PHOSPHATASE CONTENT OF NORMAL MALE URINE

The most likely explanation of these results appears to be the presence in urine of one or more substances inhibitory to acid phosphatase. The variation in the dilution effect shown by different urines would then be due to the presence of different amounts of the inhibitory substance. Investigations on this point are now in progress. Until such inhibitors can be identified and eliminated from urine, it would appear that values for urinary acid phosphatase based on measurements at one dilution only must be regarded as provisional.

We should like to thank Dr. A. S. V. Burgen for helpful discussion and for showing us some of his unpublished results.

Trace Elements and Nitrification

THE exact requirements of the nitrifying bacteria for inorganic nutrients are not yet known, though all workers on this group since Winogradsky[1] have assumed that they require iron, and many workers have added traces of other metals to their media[2], or used tap-water as a diluent, because of the possible trace elements it contains[3]. One of us has recently discovered[4], by the percolation method[5], that copper is apparently essential for nitrification in soil, so we decided to try the effect of iron and copper, alone and with other trace elements, on nitrite formation in cultures of nitrifying bacteria.

The cultures were grown at 25° C. in shallow layers of the following *liquid* medium : $M/200$ sodium chloride, $M/1,000$ magnesium sulphate, $M/1,000$ potassium dihydrogen phosphate, $M/200$ ammonium sulphate, dissolved in glass-distilled water, with 1 gm. calcium carbonate added to every 100 ml. They were not pure cultures, but must have contained a large population of nitrifying bacteria, as rapid and complete nitrification took place in them, the ammonia in the medium being converted first to nitrite and then to nitrate. The *inoculum* in the first experiment was taken from an active culture, the fourth transfer of a series in liquid media. The parent culture was obtained by incubating a small quantity of Rothamsted soil in Winogradsky's medium[1]; two serial transfers were later made to Winogradsky's medium, and two to the more dilute liquid medium described above. The *volume* of inoculum in the first experiment was only 8 drops to 100 ml. of medium; as nitrite formation was delayed in this case, the volume of inoculum was increased to 1 ml. in the other experiments, which were inoculated in each case from one of the control flasks of the previous experiment.

Salts of iron, zinc and copper were added to the medium to give the following quantities: iron

600 µgm., zinc 13 µgm., copper 14 µgm. per 100 ml. In the first experiment only, copper was added to two flasks at the rate of 28 µgm. per 100 ml. Nitrite was estimated colorimetrically with the Griess–Ilosvay reagent[5]; each figure is the mean of determinations on duplicate cultures.

Treatment	Experiment 1 11 days incubation Nitrite		Experiment 2 5 days incubation Nitrite		7 days incubation Nitrite	
	mgm. N/l.	% of control	mgm. N/l.	% of control	mgm. N/l.	% of control
Control	18	100	18·5	100	99	100
Iron	28	156	31·5	170	114	115
Copper 14 µgm.	21	117	27·5	149	80	81
Copper 28 µgm.	21	117	—	—	—	—
Iron + copper	34·5	192	22·5	122	94	95
Iron, copper and zinc	36·5	203	33·5	181	110	111

In a second pair of experiments the same three metals were added, together with a trace-element solution[6], supplying lithium, boron, aluminium, tin, manganese, nickel, cobalt, titanium, iodine and bromine. Iron was included in the medium in one experiment, and omitted in the other.

Treatment	Experiment 3 11 days incubation Nitrite	
	mgm. N/l.	% of control
Control	41	100
Trace elements only	20	49
Trace elements + zinc	22	54
Trace elements + copper	39	95
Trace elements, copper, zinc	34	83

Treatment	Experiment 4 10 days incubation Nitrite	
	mgm. N/l.	% of control
Iron only	125	305
Iron + trace elements	44	108
Iron, trace elements, zinc	45	110
Iron, trace elements, copper	94	230
Iron, trace elements, copper, zinc	99	241

The requirements of the nitrifying bacteria for elements such as iron and copper must be extremely small, as nitrite was formed in the control cultures, which must have contained the merest accidental traces of any of them. Also, as the medium contained an excess of calcium carbonate, only a very small proportion of the heavy metals added can have been in solution, and it is impossible to tell how much of the added elements were actually available to the bacteria. The outstanding feature of these results is the stimulating effect of iron; while mixtures of iron and copper, or iron, copper and zinc, had no more effect than iron alone. The unbalanced mixture of trace elements had an inhibiting effect on nitrite formation, which was not removed by zinc, but was removed by iron or copper. But the trace-element mixture with iron and copper, or iron, copper and zinc, had a stimulating effect. It appears probable that a proper balance of inorganic nutrients is more important for nitrification than the quantity of any one nutrient available.

Vascular Patterns in the Testis, with Particular Reference to *Macropus*

IN the course of a comparative study of the vascular supply of the testis in mammals, a remarkable variety of patterns of the testicular artery in the spermatic cord and on the free surface of the organ has been revealed by radiography after the injection of colloidal bismuth and 'Wettal'[1]. Some of these findings are in agreement with those of earlier workers[2–6].

In all animals so far examined, except man and the wallaby, the testicular artery before reaching the testis undergoes a tortuous convolution. On reaching the testis, it does not pass into it at the mediastinum (as commonly stated in text-books), but ramifies over the free surface of the gland on the deep aspect of the tunica albuginea in a variable pattern. Thus, in the rabbit, the white-spotted squirrel and Bosman's potto (*Perodicticus potto*), the artery may encircle the gland two or three times before giving off any branches to the testis parenchyma, while in the rat, porcupine, ram, bull and rhesus monkey it describes a series of zig-zagging convolutions on the surface of the testis before supplying the gland.

The most interesting pattern in the spermatic cord and on the testis is, however, seen in the wallaby, *Macropus rufogrisea fruticus*. The single artery, near the testis, divides into no less than ninety-six separate branches which pass down to the organ without anastomosing (Fig. 1), to reach the mediastinum and then join again to form three to four vessels which ramify over the posterior surface of the testis in arborizing fashion. The veins are collected in a similar pattern from the anterior surface of the testis and pass over the superior pole to collect at the mediastinum. From here a pampiniform plexus of about a hundred veins passes up the spermatic cord. In the transverse section of the cord shown in Fig. 2 (× 9) the numerous branches of the testicular artery, containing colloidal bismuth injection, are seen intermingled with the veins of the pampiniform plexus. This remarkable branching of the testicular artery to form a sort of 'rete mirabile' may possibly be a marsupial characteristic; but further material will need to be examined before this can be determined.

Despite the diversity of pattern of the testicular artery in the spermatic cord and on the testis in

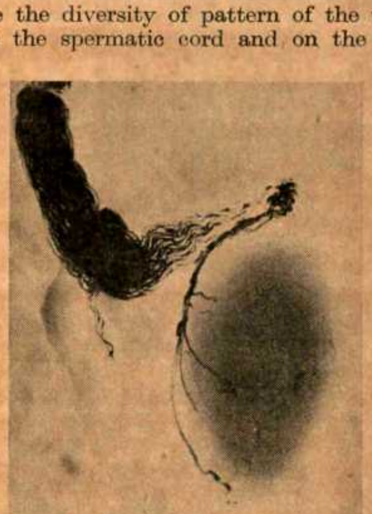

Fig. 1. A RADIOGRAPH OF THE TESTIS AND SPERMATIC CORD INJECTED WITH COLLOIDAL BISMUTH AND 'WETTAL' THROUGH THE TESTICULAR ARTERY BEFORE DIVISION. NATURAL SIZE

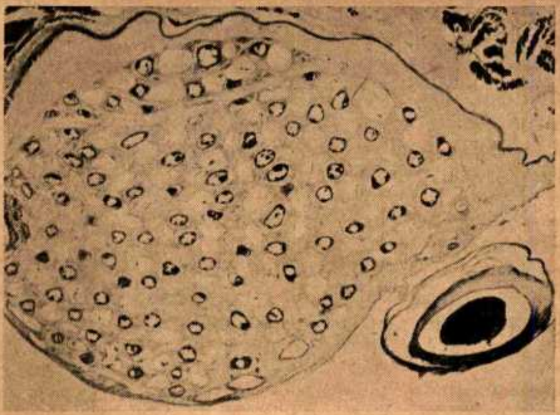

Fig. 2. TRANSVERSE SECTION OF THE SPERMATIC CORD. × 9

different mammals, it seems that the different arrangements possibly have a common functional significance, namely, to provide a mechanism for the exchange of heat in the temperature control of the testis. Experiments to test this inference are now being undertaken.

Relationships in the Plumbaginaceæ

POLLEN- and associated stigma-dimorphism within the family Plumbaginaceæ were discovered in 1883 by McCleod[1], who observed them in *Limonium*. Since then, the range of genera showing pollen-dimorphism has been extended by various authors[2–5] to include *Armeria*, *Acantholimon* and *Limoniastrum*, while stigma-dimorphism has also been demonstrated in *Armeria*[3,4].

I have made a survey of all genera within the family and have established that the clear pollen-dimorphism is found only within the tribe Staticeæ, where there is no reason for believing that it has arisen more than once. The tribe Plumbagineæ contains only pollen-monomorphic genera, and there is evidence that this monomorphism is primitive. Extreme modification in embryo-sac structure is typical of the Plumbagineæ[6] but not of the Staticeæ, so that the direct derivation of the latter from the former is not possible. It is probable that the two tribes represent diverging lines from a common (but very ancient) ancestral stock. Within the Staticeæ, *Ægialitis* is unique in showing pollen-monomorphism with grains which are probably of the same type as in the Plumbagineæ. This genus is likely to be more ancient than any others within its tribe and therefore to have diverged least from the Plumbagineæ.

In the remaining genera of the Staticeæ, pollen-dimorphism appears to be intimately connected with a genetically determined incompatibility mechanism. Derived monomorphism, however, occurs in *Limonium* and *Armeria* at least and appears to be connected, here, with self-compatibility, which may be of use in regions where pollinating insects are sparsely represented and also in facilitating establishment after long-distance dispersal.

Heterostyly occurs in *Limonium*[7], and in the Plumbagineæ[7,8], but there is some slight evidence that the development of the incompatibility mechanism made visible by pollen- and stigma-dimorphism has preceded heterostyly in the Staticeæ. If this be true, heterostyly in the two tribes would have resulted from parallel evolution.

The detailed results of these and other studies within the family will be published elsewhere in a series of papers, but this further extension of the use of pollen-morphology to indicate relationships is possibly of general interest.

Pharmacology of Ch'ang Shan *(Dichroa febrifuga)*, a Chinese Antimalarial Herb

FOR centuries in China the roots (Ch'ang Shan) and the leaves (Shuu Chi) of *Dichroa febrifuga*, Lour. have been used against malarial fevers. In our first report[1] in 1943, it was recorded that a crude extract of this root had been effectively used on clinical cases of tertian malaria. Then in 1945, when *Plasmodium gallinaceum* became available to us, we found that the crude extracts of both the root and the leaves of the herb were also effective for chicks infected with *P. gallinaceum*, the leaves being about five times as active as the roots. An alkaloidal fraction of the root exhibited a marked antimalarial activity, but of the three alkaloids, F (later called dichroine A), G and I, and two neutral principles, E (later dichrin A) and H (later dichrin B), none was found active[2]. In the following year we announced the isolation of an active alkaloid, dichroine B, melting at 237–238° C. with decomposition (considered as hydrochloride at first, later identified as dihydrochloride). It was effective against chicken malaria in intramuscular doses of 2–4 mgm./kgm. twice or thrice a day[3]. The empirical formula of dichroine B was first reported as $C_{16}H_{19}O_3N_3$ [4], and later as $C_{16}H_{21}O_3N_3$ when purer batches were examined[5]. As reported to the general conference of the Chinese Physiological Society on May 14, 1947, we had thus far isolated from Ch'ang Shan altogether five alkaloids and two neutral principles. Among the five alkaloids, dichroine A, dichroine B, dichroine C, dichroidine and quinazolone (4-keto-dihydroquinazoline), the first three members were soon found to be isomers mutually convertible under certain conditions. In conformity with the conventional nomenclature of isomers, they have been, thenceforth, called dichroine-α, dichroine-β, and dichroine-γ respectively[5]. With the probable exception of dichroine-α, all these alkaloids are more or less effective against *P. gallinaceum* infection in chicks, their antimalarial activity being in the descending order as follows: dichroine-γ, dichroine-β, dichroidine and quinazolone. From analytical studies of the oxidation products of dichroine-α, it is apparent that the dichroine isomers are quinazoline derivatives. Of the two neutral principles, dichrin *A* and dichrin *B*, the first has been identified as umbelliferone. In the accompanying table, the chemical and pharmacological properties of these seven substances from *Dichroa febrifuga* are summarized.

Principle	Formula	M.p.	*L.D.*50, mice. I.V. (mgm./kgm.)	Antimalarial activity, *P. gallinaceum*, (mgm./kgm.)
Dichroine-α	$C_{16}H_{21}O_3N_3$	136	18·5	Ineffective up to 8 mgm.
Sulphate		230*†

Quinazolone	$C_8H_6ON_2$	212		
Hydrochloride		250		
Dichrin *A* (Umbelliferone)		228–230		Ineffective up to 4 mgm.
Dichrin *B*		179–181		Ineffective up to 4 mgm.

* Crystallizing from water. † Melting with decomposition.

We also wish to state that another Chinese herb, Tou Ch'ang Shan, exhibits potent antimalarial action on chicken malaria. This herb has been tentatively identified as *Hydrangea umbellata*, Rheder., belonging to the same family (Saxifragacea) as *Dichroa febrifuga*. Its active fraction has been found to be also alkaloidal in nature, and several crystalline alkaloids have been isolated.

[5] Chou, T. Q., Fu, F. Y., and Kao, Y. S., *J. Amer. Chem. Soc.* (in the press).

Three further references to work on *Dichroa febrifuga* can be added to those quoted above: they are Tonkin and Work, *Nature*, 156, 630 (1945); Cheng Fang Tsu, *J. Trop. Med. and Hyg.*, 75 (April, 1947); and J. B. Koepfli, J. F. Mead and J. A. Brockman, *J. Amer. Chem. Soc.*, 69, 1837 (1947). Dr. Koepfli refers to the earlier work of Dr. Jang and directs attention to the disparity in melting point between his own and Dr. Jang's active alkaloid. The new results now presented by Dr. Jang do not resolve this difficulty. Dr. Koepfli suggests, however, that, at any rate in leaf, the biological activity is not accounted for by the active alkaloid which he isolated; thus several related bases may be present. It should also be noted that Dr. Koepfli suggested the active principle was a quinazoline derivative, a conclusion which is now reached by Dr. Jang also.

Annealing of Glass

It is well known that the relaxation of stress in glass during annealing does not follow the Maxwellian relaxation formula. Indeed, annealing schedules for glass are always based on Adams and Williamson's[1] empirical law that the reciprocal of the stress is proportional to the time. Littleton[2] and Lillie[3] have attempted to account for the discrepancy on the basis of the viscosity being a function of the time, and many workers have attributed it to the dependence of the stress relaxation on some 'molecular viscosity' or upon changes in the equilibrium state of the glass.

If the change in the state of glass associated with temperatures about and above the annealing range is pictured as the development of 'holes' (or the equivalent concept, the development of two-positioned sites for some of the ions[4]) with increasing temperature, one can express the number of such holes as a function of temperature and pressure for equilibrium, and, by a treatment similar to that used in calculating the rates of crystal growth[5], one can find the rate of approach to equilibrium. Thus an equation for the stress relaxation may be derived:

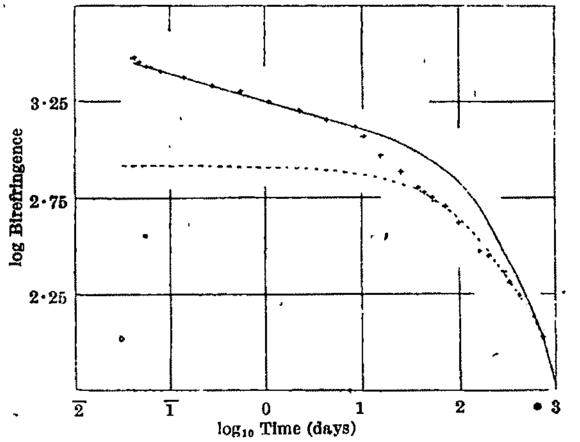
$$\log S_0/S = at + b \log \{1 + D(1 - \text{expt.-wt.})\}.$$

At low temperature (430° C.) 'W' is very small, so that provided the time is not too long:

$$\log S_0/S = at + b \log (1 + ct),$$

where S_0 and S are the initial and subsequent stresses and t is the time.

In this expression the constant a is inversely proportional to the viscosity, and no allowance is made



for variation of viscosity with time, although such is to be expected because of the changing state of the glass. While the first term on the right-hand side has a form similar to Maxwell's relaxation, the constant a differs from his expression rigidity/viscosity by virtue of the 'hunting' action of the pressure-sensitive equilibrium upon the stress.

Morey's[6] experimental results for 'Pyrex' chemical resistance glass at 430° C., which extended over two years, are shown in the graph, where both stress (birefringence) and time are plotted as logarithms. The full curve is calculated from the expression above, while the stress calculated from the empirical law according to Adams and Williamson is dotted.

Inspection will show that the departure of the continuous line from the observed values is such as would be expected from neglect of viscosity variation.

Adams and Williamson's law holds only over a small part of the total time range, and is therefore of little theoretical significance. Its value lies in that it holds over just that range of time which is of practical importance.

Determination of Silicate Inclusions in Steel

THE appearance of non-metallic inclusions and their influence on the mechanical and corrosion properties of steel have been the subject of many investigations[1,2]. For the determination of silicate inclusions, many methods (chlorine, bromine, iodine and electrolytic) have been used successfully. But they are all rather difficult; other simpler methods, such as the dissolution of the steel sample in nitric, hydrochloric or sulphuric acids, give uncertain results. In the search for a simple method, we used the dissolution of steel in acetic acid.

The treatment worked out by us is in outline as follows: 20 gm. very fine drillings of unhardened steel (hardened steel gives results which are too high on account of the adsorption of silicic acid on carbon) are put into 500 c.c. of 2 N acetic acid in an Erlenmayer flask. The flask has a stopper with two tubes, through one of which nitrogen is introduced (or other indifferent gas) free of oxygen; the nitrogen passes through the acid and escapes by the second outlet. The flask is put on a boiling water bath and, when the drillings are dissolved (for very fine drillings it takes three to four hours), the solution is decanted through a fine filter (Schleicher and Schüll, Blau Band) in a Buchner funnel, washed with distilled water, then with 3 per cent solution of sodium carbonate and finally with hot distilled water. The filter with the residue is ignited in a platinum crucible. Then we determine silicon dioxide in the ash in one of the usual ways; or (1) after melting it with sodium carbonate, or (2) by expelling the SiO_2 by heating the residue with a mixture of hydrofluoric and sulphuric acids after previous treatment of the residue with a mixture of hydrochloric and nitric acids (in order to remove the greater part of iron oxides). In the remaining oxides we can determine the Al_2O_3 content of the steel.

To test the method we determined the SiO_2 content of seven steels, the compositions of which are shown in Table 1.

TABLE 1. COMPOSITION OF STEELS (PER CENT)

Number of steel	C	Si	Mn	P	S
1	0·14	0·14	0·46	0·014	0·028
2	0·40	0·35	0·60	0·021	0·010
3	0·46	0·30	0·62	0·021	0·026
4	0·57	0·24	0·57	0·033	0·042
5	0·65	0·30	0·70	0·037	0·026
6	0·98	0·16	0·32	0·024	0·010
7	1·09	0·29	0·19	—	0·008

In Table 2 are summarized the results of determinations of SiO_2 by the chlorine, bromine, electrolytic (Benedicks – Skapski) and the method described above. The results of the chlorine, bromine and electrolytic methods are average results.

TABLE 2. PERCENTAGE OF SiO_2 IN STEELS

Number of steel	Chlorine method	Bromine method	Electrolytic method	Acetic method	
					Mean
1	0·021	0·019	0·0185	0·020 0·018 0·020	0·0193
2	0·0115	0·015	0·0097	0·012 0·010 0·009	0·0103
3	0·0055	0·0055	0·005	0·005 0·006 0·004	0·0050
4	—	0·007	0·006	0·008 0·006 0·006	0·0067
5	—	0·0105	0·014	0·013 0·012 0·013	0·0127
6	0·005	0·008	0·0085	0·008 0·008 0·007 0·007	0·0075
7	0·0023	0·0032	0·00325	0·0030 0·0029 0·0032	0·00303

The agreement of the results obtained by the new method with those by generally accepted methods is quite satisfactory. The determination of the Al_2O_3 content in steel gives good results, too, in comparison with the results obtained by the dissolution in nitric acid or electrolytic dissolution.

A detailed description of the method will be published in the near future.

Extinction of Petrol Fires by Methyl Iodide

THE distressing and increasingly frequent incidence of fatal fires in tankers, aeroplanes and other petrol-using machines, and in factories and laboratories employing fuels and inflammable solvents, has repeatedly directed attention to the need for a quick quenching agent. In such straits, so long as they contain carbon tetrachloride, the brass squirts so universally carried are of less use than mascots. This substance will not extinguish petrol fires. At best, it may localize the combustion. It yields stifling clouds of black soot and twice its own vapour-volume of chlorine. It is itself toxic.

As a young man, I worked as an assistant both to R. V. Wheeler and to H. B. Dixon, and it has occurred to me to follow up the latter's investigation of the former's discovery of the combustion-inhibiting influence of the iodides. One of many reasons for the choice of methyl iodide for the initial experiments was its physical resemblance to carbon tetrachloride. Chemically and physiologically it is very different. It is safer and pleasanter in use; and it does not yield noxious or corrosive end-products.

It was found that in all cases where carbon tetrachloride was effective, methyl iodide was equally effective with one fifth of the quantity. Both were better sprayed than squirted, and the pumps and syringes needed non-greasy lubrication. The crucial experiment was then tried of spraying it on to a water-borne layer of petrol on fire. Up to forty square feet, garden syringes were used. Over greater areas a pump was desirable. This test gave a complete failure to carbon tetrachloride, a saturated water solution of ammonium iodide and to methylene di-iodide. These substances burnt in the flames. Under a spray of methyl iodide, however, the petrol flames broke, wilted and withered. There was no smothering or swamping; the effect resembled that of a policeman's hand on traffic. Moreover, the petrol can at will be repeatedly rekindled and requenched until it is made safe or exhausted.

Tray-fires of ether, methylated spirits, and white spirit, which could not be extinguished by carbon tetrachloride, were swiftly quelled by methyl iodide.

Some hundreds of comparisons made, less picturesquely, with a flash-point apparatus contain no single exception to this overwhelming superiority of methyl iodide.

This fact has immense possibilities in social consequences—the price, of course, must fall just as the price of *D.D.T.* fell. What it amounts to in physical chemistry seems to be a fascinating example of how combustion-chains may be affected by iodine atoms freshly liberated from a single valency. The iodine, liberated in the burning of methylene di-iodide would clearly seem to have a different mode of existence.

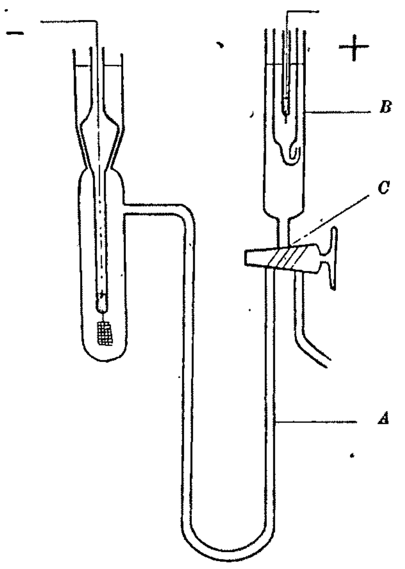
A Simple Moving-Boundary Apparatus

IN the conventional types of apparatus for the measurement of transference numbers in electrolyte solutions by the moving-boundary method, elaborate devices are used to achieve the initial formation of a reasonably sharp boundary[1,2]. It seems surprisingly to have escaped notice so far that a sharp 'sheared' boundary can be formed satisfactorily and with less trouble by the use of a single three-way tap of good quality.

The apparatus used by us, illustrated in the accompanying figure, has been designed for the measurement of the transference number of hydrogen ion in hydrochloric acid solutions by a descending boundary in the tube *A*, using lithium chloride as the 'indicator' electrolyte. The adaptation of the principle to other measurements is obvious.



The whole apparatus is first filled with the hydrochloric acid solution with the tap in the position connecting *A* and *B*, after which the anode vessel is emptied (by turning the tap through 180°). *B* can then be rinsed through with the indicator solution at leisure. After turning the tap through 90°, *B* is filled with the indicator solution and, on connecting *A* and *B* again by turning the tap to the initial position, a sharp boundary is formed at *C* the velocity of which may be measured after it has passed through the tap.

We wish to thank Messrs. E. C. A. Horner and A. D. Jenkins for experimental assistance.

Elminius modestus in the Netherlands

RECENTLY, Jones[1] remarked that the barnacle *Elminius modestus* Darwin, if introduced into France and Holland, is likely to become particularly troublesome for the oyster culture industry. It may be worth while to state that the species seems to be already fairly common in the southern part of the North Sea coast of the Netherlands.

As Bishop[2] stated that the barnacle was taken from the hull of the M.V. *Empire Wansbeck*, which had been plying between Harwich and the Hook of Holland, the species might be expected here. To direct attention to its probable occurrence, a note giving particulars of the barnacle was inserted in a stencilled periodical devoted to the study of the seashore, and the Leyden Museum soon received material of *Elminius* from Scheveningen and its surroundings and from Serooskerke in Zeeland. The first specimens on flotsam were collected on September 19, 1946; the first specimens on piles were obtained on October

18, 1947. The latter, therefore, undoubtedly have developed from larvæ occurring in Dutch waters.

What is a Dialysate ?

IN *Nature* of November 22, 1947, p. 720, H. G. Derx has commented upon the confusion caused by the lack of a suitable name for the material retained by a dialysing membrane. He has proposed the use of the term 'residue'. We have found the term 'impermeate', coined by Dr. Howard Eder in our laboratories some years ago, a very descriptive and helpful one to apply to such material

Operational Research

IN spite of the frequency with which operational research has been referred to recently, there are extremely few published discussions from which the layman can obtain an idea of what it is[1]. Its nature is actually extremely straightforward; the very simplicity of the basic idea is probably one of the reasons why many people seem to find it so difficult to grasp. In the first place, operational research is research in the true sense. I would refer to Blackett's obituary notice of E. J. Williams[2], in which he tells how Williams found the phenomena of U-boat warfare as intellectually enthralling as those of atomic physics; and Williams could scarcely have been accused of not knowing what scientific research really means. The adjective 'operational' does not mean that the activity is not true research, any more than do the adjectives in such expressions as 'chemical research', 'genetical research', etc. It characterizes, not the quality of the research, but its subject-matter, which was originally the operations of armed forces. In a wider definition, operational research can be described as the application of the methods of scientific research to the study of the problems which face an executive authority.

The special characteristic which differentiates operational research from other branches of applied science is that it takes as the phenomenon to be studied the whole executive problem and not the individual technical parts; its interest may be focused, for example, on 'how to find U-boats from aircraft', while specialist applied sciences would be studying component parts of the situation, such as the physics of radar, the psycho-physiology of fatigue, etc. It is, perhaps, because operational research scientific workers had to depend so largely for detailed information on the generous collaboration of their specialist colleagues that some people appear to think that they invented new techniques of teamwork. How badly the world needs such techniques ! But it is for the sociologists, not the operational research workers, to discover them.

In point of fact, operational research possesses no new or special technique of its own. It uses the normal methods of scientific research to discover the facts about the phenomena which it is studying. Naturally, some of science's armoury of methods are more appropriate to its subject-matter than are others, just as genetical research often calls for statistical methods, while experimental embryology finds more use for manipulative skill. But it has no secret weapon.

Why, then, it may be asked, is it important to consider whether sufficient use is being made of operational research during peace ? The answer, I think, is that although the methods of operational research are not new, the direct application of those methods to executive problems had only been made very spasmodically before the War, and, when undertaken on a reasonably large scale, proved itself to be extremely fruitful. The Services, which, on the fighting side, have an organisation designed for the specific purpose of deciding what to do and then doing it, soon recognized the difference between analysing the situation (operational research), drawing up a scheme to cope with it (planning) and putting the scheme into effect (operations), and possessed a framework into which the first of these could easily be fitted. The civil branches of government, which have only recently been called upon to initiate and carry out major enterprises, seem to find these distinctions more difficult to grasp ; and we find *Nature* implying that operational research is a method of planning[3]. Research by itself can never produce a plan ; its function is to prepare the basis on which a rational plan can be founded, by identifying qualitatively the factors in the situation, and, as far as possible, by evaluating them quantitatively. It seems to me astonishing that any scientific worker should doubt that the scientific method is by far the most powerful instrument we have for performing the analysis and fact-finding on which executive decisions should be based. Surely no one could be satisfied to try to "re-deploy the scientific effort of Great Britain" without trying first to find what the probable demands are in the various fields ; what the available resources are, and would become ; how many men of science could function equally well if re-directed into other fields ; for what reasons scientific workers have taken up the work they are now doing ; what the demands on teaching establishments would be to achieve different rates of redeployment ; and so on. Investigations of this nature, which would take into account all the factors which could be shown, or surmised, to influence the situation, would be equally necessary whether the planners eventually decided to put their schemes into effect by a totalitarian *fiat*, or by any of the gamut of subtler systems of payments and incentives. A beginning should be made with them, even though one believes that the brute facts, like Archimedes' tortoise, can never be completely overtaken by scientific analysis. But it only obscures the issue if consideration of the importance of research on behalf of the executive planners is prejudiced by opinions as to the method by which the plan should be put into operation.

A FACTOR IN HEART MUSCLE REQUIRED FOR THE REDUCTION OF CYTOCHROME *c* BY CYTOCHROME *b*

By E. C. SLATER

Molteno Institute, University of Cambridge

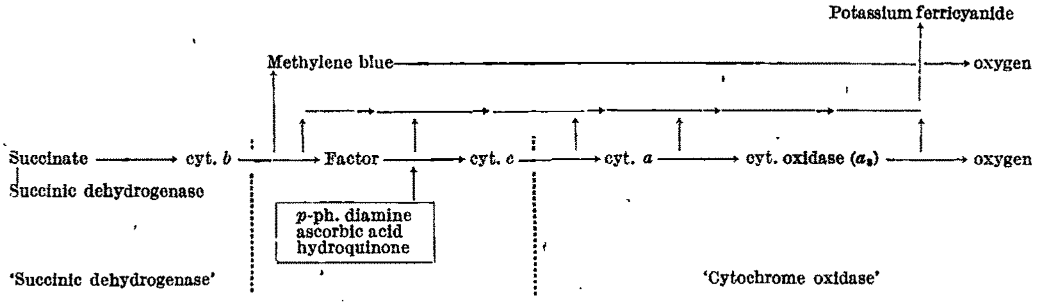
IT is well established[1] that the intracellular respiratory complex catalysing the aerobic oxidation of succinate (the succinic oxidase system) includes the cytochrome system in addition to the specific enzyme responsible for the activation of succinate (that is, succinic dehydrogenase). Thus the transport of electrons from succinate to molecular oxygen proceeds through a chain of electron carriers of successively higher oxidation-reduction potential[2]. Four such carriers have been identified spectroscopically, namely, cytochromes *b*, *c*, *a* and a_3. Cytochrome a_3 is probably identical with cytochrome oxidase[3]. The purpose of the present communication is to present evidence for the existence of an additional carrier. This evidence was obtained by studying the mechanism of the action of certain reducing agents (particularly the dithiol 2,3 dimercaptopropanol (*B.A.L.*)) on the succinic oxidase system of heart muscle.

It was found that the oxidation of this dithiol by air at *p*H 7·1 was catalysed by the heart-muscle preparation of Keilin and Hartree[1]. Treatment of the heart-muscle preparation with *B.A.L.*, in the presence of air, had two quite distinct effects on the enzymes responsible for the oxidation of succinate: (*a*) Complete inactivation of the succinic oxidase system (measured by the rate of oxidation of succinate in the presence of excess cytochrome *c*), without any effect on the succinic dehydrogenase (measured by the rate of oxidation of succinate in the presence of methylene blue and potassium cyanide); this inactivation is complete soon after the addition of the *B.A.L.* (*b*) A partial inhibition of succinic dehydrogenase, which does not occur until more than half the *B.A.L.* is oxidized; this inhibition is probably largely due to the action of oxidized *B.A.L.* on the sulphydryl groups of succinic dehydrogenase (cf. Hopkins and Morgan[4]). Incidentally, these observations reconcile the apparently divergent findings of Barron *et al.*[5] and of Webb and van Heyningen[6] on the action of *B.A.L.* on the succinic oxidase system, since the former workers measured the effect on the complete succinic oxidase system, whereas the latter studied the effect on the succinic dehydrogenase alone.

The inactivation of the complete system without concomitant inhibition of succinic dehydrogenase was produced only if *B.A.L.* was oxidized in air in the presence of the enzyme. No inhibition resulted from contact with the dithiol under anaerobic conditions, while oxidized *B.A.L.* only slightly inhibited the succinic oxidase system and at the same time inhibited succinic dehydrogenase. Although it was found that hydrogen peroxide was produced during the oxidation of the *B.A.L.*, the effect on the enzyme was not due non-specifically to this hydrogen peroxide, since hydrogen peroxide produced by other systems (notatin-glucose; *d*-amino-acid oxidase and its substrates) inactivated the enzyme only partially, and this inactivation, but not the *B.A.L.*-induced inactivation, could be partly protected by alcohol and by pyruvate and was increased by catalase. Moreover, the addition of copper, which increased the rate of oxidation of *B.A.L.* and, therefore, the rate of production of hydrogen peroxide, decreased the degree of inactivation.

Treatment of the heart-muscle preparation with *B.A.L.* under conditions which led to complete inactivation of the succinic oxidase system had very little effect (about 10 per cent inhibition) on the cytochrome oxidase activity (measured by the rate of oxidation of ascorbic acid, hydroquinone or *p*-phenylene diamine in the presence of excess cytochrome *c*). The ability of the heart-muscle preparation to catalyse the oxidation of *p*-phenylene diamine in the absence of added cytochrome *c*[7] was inhibited by about 35 per cent by the same treatment.

This treatment with *B.A.L.* did not affect the intensities of the cytochrome $a + a_3$, *b* and *c* bands, after reduction with sodium hydrosulphite, showing that the amounts of these cytochromes were not altered. When, however, succinate was added instead of sodium hydrosulphite, an impairment of the rate of oxidation of cytochrome *b* by cytochrome *c* was observed: thus on adding succinate to heart-muscle preparation treated with *B.A.L.* and shaking with air, the *b*-band alone was visible, that is, in the reduced state (cf. the action of narcotics[1]). The cytochrome *b* could, however, be oxidized by the addition of methylene blue or dichlorphenol indophenol. Although cytochromes $a + a_3$, *b*, *c*, were not destroyed by *B.A.L.*, the total hæmatin content (measured by the intensity of the pyridine-hæmochromogen band at 548–560 mμ after the addition of sodium hydrosulphite and pyridine) was reduced by about 20 per cent when the succinic oxidase system was completely inactivated. Thus treatment with *B.A.L.* destroyed some hæmatin compound the spectrum of which is not visible in the heart muscle preparation, either before or after treatment with hydrosulphite. There was a close correlation between the amount of hæmatin compound destroyed and the



THE COMPONENTS OF THE SUCCINIC OXIDASE SYSTEM degree of inactivation of the succinic oxidase system when different concentrations of *B.A.L.* were allowed to act on the enzyme for various times.

The enzyme preparation after treatment with *B.A.L.* could not be reactivated by catalase, cytochrome *c*, serum proteins, denatured globin, calcium phosphate gel, Straub's '*SC* factor'[8], copper, aqueous extract of fresh heart-muscle mince (rich in myoglobin) or various fractions of the heart muscle preparation. The enzyme could, however, be protected from the action of *B.A.L.* by the presence, during treatment, of cytochrome *c*, which caused rapid oxidation (through the cytochrome oxidase system) of the dithiol.

Treatment with *B.A.L.* under conditions which caused complete inactivation of the succinic oxidase system, with about 10 per cent inhibition of succinic dehydrogenase, inhibited the activity of the system, measured anaerobically by the rate of reduction of ferricyanide, by 35 per cent.

These observations suggest the existence of a *B.A.L.*-labile factor, probably a hæmatin compound, which transfers electrons from cytochrome *b* to cytochrome *c* and is destroyed by coupled oxidation with reducing agents (cf. the action of ascorbic acid on hæmoglobin, Lemberg *et al.*[9]) when the heart-muscle preparation is treated with reducing agents in the presence of air.

The relationships between this factor and the cytochromes are shown in the accompanying scheme, the arrows showing direction of electron transfer. Thus destruction of the factor would not affect the oxidation of succinate through methylene blue as carrier, nor the oxidation of various reducing agents through cytochromes *c* and *a* and cytochrome oxidase; but would prevent completely the transfer of electrons from cytochrome *b* to cytochrome *c* and thence to molecular oxygen. It is postulated that potassium ferricyanide, with an oxidation-reduction potential (E'_0 at pH 7·3 $= + 0{\cdot}41$ V.) much higher than that of succinate $\rightleftharpoons$ fumarate (E'_0 at pH 7·3 $= -0{\cdot}01$ V.) or of cytochrome *b* (E'_0 at pH 7·3 $= - 0{\cdot}04$ V.) operates partly directly with cytochrome *b* and partly through the *B.A.L.*-labile factor or the cytochromes of higher oxidation-reduction potential (E'_0 of cytochrome $c = + 0{\cdot}26$ V., cytochrome $a = + 0{\cdot}29$ V.). Thus the destruction of the factor causes a partial, but not complete, inhibition of the rate of oxidation by ferricyanide.

It is possible that the factor is the same as, or closely related to, the component *X* suggested by Bach *et* al.[10] to be necessary for the reduction of cytochrome *c* by cytochrome b_2 in yeast.

The complete experimental data and a discussion of these findings in relation to previous work on the succinic oxidase system will appear elsewhere.

I would like to express my sincere thanks to Prof. D. Keilin for his most valuable advice throughout this investigation. I also wish to thank the British Council for a scholarship.

PLANT ANALYSIS AND FERTILIZER REQUIREMENTS

A QUICK and reliable method of determining the fertilizer requirements of crops and of discovering what nutrient deficiency is responsible for the unsatisfactory growth of some particular crop would be of immense value in advisory work. The problem can be approached from several different points of view, such as soil analysis, field trials, pot cultures, leaf injection, plant analysis and the use of visual symptoms. The relative advantages and disadvantages of these various methods of diagnosing fertilizer requirements are briefly but clearly summarized in the paper under notice*, and an extensive list of references facilitates fuller study of the individual methods.

A short historical account of the early work on diagnostic plant analysis reminds the reader that there is much to be learnt from these early papers. Developments during the past twenty-five years are discussed in more detail, and a great deal of information on the content of nutrients in plant material in relation to the incidence of deficiency or toxicity symptoms is summarized in tabular form.

Reference is also made to the use of plant analysis in the determination of current nutrient requirements by so-called 'tissue tests'. Carried out on sap or extracts of fresh material, it is suggested that the fractions estimated by these tissue tests are mainly unassimilated material which has recently entered the plant and that their concentration thus represents the *current* rate of nutrient intake. The rapidity with which 'tissue tests' can be performed and the fact that their results can be translated into immediate fertilizer treatment quickly enough to be effective even on annual crops, provided the problem is recognized early in the life of the crop, makes them specially attractive in advisory work. If they can be shown to be reasonably reliable and their interpretation does not require the establishment of a very elaborate series of standards, they seem likely to displace some of the older methods used in advisory work.

As the authors of this paper point out, when defining the aim of a method of deficiency diagnosis, there is an important distinction between methods to be used to improve the nutrition, during the course of its growth, of the crop analysed, and those where the plants analysed serve only as an index of the state of the soil and as a guide to the best fertilizer treatment for subsequent crops.

In a discussion of the relation of internal nutrient concentration to nutrient supply, evidence from barley grown in sand cultures, to which nutrients were added before germination, is used to show that: (1) the concentration in the tissues will depend upon the time during development at which determinations are made; and (2) the results will depend upon the part of the plant chosen for analysis. Analysis of the plant soon after germination (when the seed reserves are exhausted) will give some measure of the concentration of the nutrients in the rooting medium, especially in plants like cereals that branch very rapidly in the early stages.

The bearing of these facts on the relations to be expected with plants growing in the field are complicated by the difference in the mode of supply of the nutrient; for not only are the differences in the concentration of the nutrient in the field of a different order from those in the sand cultures described, but also rates at which nutrients in the soil become available are likely to be more important than actual concentrations in the soil solution, and the supply may continue at a relatively high level throughout the growing period. This is specially important in those types of plant, such as barley, in which nutrients taken up after the stage when further elaboration of meristems ceases lead to no further increase in yield but merely raise the concentration within the plant, thereby checking the normal tendency to decline to a minimum at harvest. Hence plant analyses from field crops can show considerable variations in concentration at harvest. High concentration of nutrient in the mature cereal plant may be due either to limitation of growth by some other nutrient factor leading to 'luxury consumption' or to a high supplying power of the soil maintained throughout the growing period. In the former case, the authors point out that yield will tend to be low and could be improved by the addition of the nutrient in minimum; but in the latter case yield will be high. Hence the use of analyses of mature cereal plants as indicators of the nutritional status of soils depends on the fact that differences in the nutrient-supplying power of the soil persist throughout the growing season, leading to accumulation at harvest, and not upon any causal relationship between final internal nutrient concentration and yield.

---

* Chemical Composition of Plants as an Index of their Nutritional Status. (Tech. Comm. No. 17, Imperial Bureau of Horticulture and Plantation Crops.) By Dr. D. W. Goodall and Dr. F. G. Gregory. Pp. 167. (Aberystwyth: Imp. Bur., 1947.) 9*s*.

A good deal of consideration is given to the best method of selecting plants for analysis, to the influence of time of day and time of year or stage of development of the plant when samples are taken, and to the advantages of analysing the whole plant as compared with a single organ of the plant. On the subject of which organ is likely to prove the most suitable for analysis, the authors have collected all the available evidence and present it in tabular form under the various crops. In the majority of cases the leaves seem to show the greatest proportional increase in internal concentration of a nutrient with increase in its supply. Necessary precautions in the preparation of material for analysis are discussed, followed by consideration of the analysis itself, including the need to determine particular chemical fractions and the choice of extraction methods.

The interpretation of the results of diagnostic analysis is perhaps the most difficult part of the whole problem of the use of plant analysis to determine fertilizer needs. Standards of reference are essential, together with data on the performance of the plants from which they are derived. To establish standard values for internal nutrient content requires data on the yield responses of plants at varying levels of nutrition and on their composition. Emphasis is placed on the dangers of basing conclusions on data for a single element without allowing for variations in the content of other nutrients. Nevertheless, it is pointed out that many investigators have specified optimal levels or limiting values above which the supply of a particular nutrient may be regarded as adequate, presumably where the content of other nutrients is not limiting. A comprehensive table of these suggested standard values for nutrient content of a wide variety of crops is included in the paper.

Suggestions by numerous workers for standard ratios of various plant nutrients are also given in tabular form; but the authors state that in their opinion there is no reason for supposing that ratios of nutrients in general are likely to be of greater use in diagnostic work than the content of the elements individually. They consider that ratios of nutrients within the plant should generally be used in conjunction with data for individual concentrations. The authors express the view that 'foliar diagnosis' work must be subject to much the same criticisms as other work involving the use of ratios.

In their final consideration of the place of plant analysis among other methods of nutritional diagnosis, the authors suggest that a combination of soil and plant analyses may give the most satisfactory results: soil analysis to determine pre-planting fertilizer treatment, and plant analysis for perennial crops and to indicate the need of annual crops for side or top dressings of fertilizer. Diagnosis by visual symptoms is an easy and rapid method where symptoms can be readily and definitely recognized, but has the disadvantage that waiting for deficiency symptoms to appear before treatment can be given may reduce the final yield.

SOCIOLOGY OF MENTAL DISEASE

THE physical and biological sciences have at last been accepted as indispensable adjuncts to the art of government, but the psychological and sociological lag behind. No clearer evidence of this is needed than the assumption that the men of science whose help should be asked to solve the problem of controlling atomic bombs are those who are specialists in making the machine rather than those who are specialists in the study of the minds likely to set the machine in motion.

It is encouraging, therefore, that the National Association for Mental Health should have had full and practical governmental support for its conference in the Seymour Hall during January 15–16. By sanctioning the payment of expenses, the various Ministries secured a very large attendance of delegates from local authorities. Moreover, the Parliamentary Secretary to the Minister of Health contributed that rarest of things—an opening address which must have usefully coloured the minds of everybody throughout the ensuing meetings.

Mr. Edwards emphasized that mental illness is a social disease with sequelæ deleterious to national and international life, that its consequences affect production drives, foreign policies, the family institution, and the efficacy of education. Moreover, it is a matter which cannot be left simply to technicians, since it affects every individual, however, sane potentially, since complete sanity is impossible for anyone who has to live in a community riddled with mental and nervous troubles.

Dr. G. R. Hargreaves, principal medical officer of Lever Bros. and Unilever, Ltd., and Dr. Donald Stewart, medical adviser to the Austin Motor Co., provided the text for the conference by epitomizing the Russell Fraser Report on the incidence of neurosis among factory workers*. In a sample of more than three thousand male and female workers in light and medium engineering factories, 10 per cent suffered from definite and disabling neurotic illness and a further 20 per cent from minor forms of neurosis during the course of six months. Neurotic illness accounted for a loss of three working days by every man studied and six days by every woman. It is at least as important a source of industrial loss as colds and influenza, or accidents and industrial disease.

---

* No. 90. Industrial Health Research Board, 1947. (H.M. Stationery Office.) 1s. 3d.

Moreover, since neurosis is a disease of human relationships, in which the sick man's associates and family suffer, there must be added an incalculable loss caused by interference with the smooth working of those who do not themselves report sick.

Dr. Hargreaves suggested that hitherto social effort has been concentrated on psychotics and serious certifiable disease too exclusively, and that so long as the whole problem outruns the supply of trained personnel it is wiser to concentrate on the lighter neurotic diseases which interfere far more with the social machine than the psychotic do.

Dr. Kenneth Soddy, medical director of the National Association for Mental Health, and Dr. Doris M. Odlum, vice-president, discussed the obligations and opportunities given to local authorities by the National Health Service Act, 1946, in dealing with this problem.

Dr. Soddy gave a series of case-histories which showed that the problem of the neurotic cannot be treated as a purely medical one, and that the psychiatric social worker has a specific task, involving the mastering of a difficult technique, to co-ordinate the various administrative organs which might be needed to cope with a socially and personally 'unstuck' individual.

It is clear that the provision of sufficient trained psychiatric social workers—one in 2,500 of the population—is virtually impossible for many years. Not only is it impossible to train this number; but also there are probably not sufficient people of the right character and temperament fit for training. It is on this problem that it was possible to sense a difference of opinion within the conference.

On one hand, Dr. Greenwood Wilson, medical officer of health at Cardiff, speaking as a delegate, said that Cardiff proposes to use health visitors to help supplement the trained psychiatric workers, and pointed out that health visitors are not only experienced in human nature, but also masters of the special technique of breaking into the family circle in quest of private and intimate information. On the other hand, Brigadier A. Torrie, director of army psychiatry, gave his opinion that only a person with psychiatric training could be entrusted with any part of the work. It is to be hoped that Brigadier Torrie is wrong, since we shall not have a hundredth part of the required army of psychiatric workers trained for years to come. Fortunately, the National Association for Mental Health is aware of the danger of establishing a vested interest point of view on this matter.

The real difficulty is that applied psychiatry involves two requisites: a technique to be acquired by a specific training, and a personal character which cannot as yet be acquired. An industrial physicist or chemist may be a drunkard, a wife-beater or a child murderer without it necessarily interfering with his scientific work; but an industrial psychiatrist can ill afford these idiosyncrasies.

Whatever it means to-day, psychology used to mean the study of the human 'soul', and there used to be a profession or a vocation called a 'cure of souls'. Why the cure of souls has been taken over from the clergyman by the psychiatrist is a question which cannot be gone into here. Possibly there are too many clergy who have character without technique, but it is certain that technique by itself will be no adequate substitute for character. The admirable speech of the Earl of Feversham, chairman of the National Association, left the conference in no doubt that the Association is fully alive to this necessity for wedding technique and character in all cure of souls, and along with Mr. Edwards' opening address must have sent the delegates away realizing that they must act not only as administrators but also as human beings if the rising tide of mental sickness is to be held back. Both Dr. Odlum and Miss Clare Britton repeatedly emphasized that good results depended on personnel who know how to be humane. Miss Britton made a good point when she suggested that personnel for boarding schools for difficult children should never be expected to spend more than seven years of their lives at this exacting task. All psychiatry involves such inroads on emotional resources, apart altogether from its demands on those parts of the human intellect usually called upon for scientific work, that it should only be practised for limited periods.

It is to be hoped that all local authorities represented at the conference will have been impressed with the opportunities afforded them under the new Act for dealing with the chronic minor diseases of human relationships which cause so much more trouble than the far rarer and more spectacular mental disorders to which their attention was once confined.

ASSOCIATION OF BRITISH ZOOLOGISTS

DESPITE the predominantly urban nature of the population of Great Britain, one of its characteristics at the present time is a reawakened interest in, and a feeling of responsibility for, the countryside. This is made more acute by the realization of the part which agricultural workers can play in supplying food, and by the fear that, in a small island like Great Britain, indiscriminate exploitation by industry or the Services might destroy what could never be replaced. That this spirit is beginning to permeate the teaching of biological subjects in both schools and universities was indicated at the meeting of the Association of British Zoologists held on January 8, in the rooms of the Zoological Society of London. Prof. H. Graham Cannon was in the chair and the general topic of discussion was "The Field Study and Conservation of the British Fauna".

The universities of Britain are, for the most part, situated in its big towns, and at present the combined difficulties of congested time-tables, large classes and inadequate staff often mean that little or no field-work can be introduced into their zoological courses. Such work of this type as has been done in the past has almost invariably been marine, and the field courses of longest standing are those held at the various marine laboratories. These, as was stressed by Prof. F. W. Rogers Brambell, must remain the most important in the training of the general zoologist; but they should be supplemented by others which would introduce the student to freshwater or entomological ecological problems, and which would provide special training in these where that is necessary. Prof. J. W. Munro described in this connexion the way in which the Silwood Park Field Station of the Imperial College of Science and Technology could be used for both undergraduate teaching and for introducing post-graduate workers to field research in entomology—a very important development if many of the schemes for the Colonies, such as that for growing groundnuts in Africa, are to be supplied with properly trained biologists. Without the help of such men, all these projects were liable to failure, with very grave consequences for both the Colonies and for Britain.

Mr. F. H. C. Butler, director of the Council for the Promotion of Field Studies, explained how this five-year-old body functions, and described how the centres which the Council operates at Flatford Mill, Juniper Hall, Malham Tarn, and Dale Fort might be used to increase the variety of types of field work now possible. These offered to school-children, university students and private individuals alike the opportunity of doing supervised work in the field on biological and related subjects, of observing the interaction of these studies and so counteracting the tendency towards over-specialization. Dr. E. A. Ennion, warden of the Council's centre at Flatford Mill, gave an account of the way in which work there is carried out, stressing in particular the precautions which are taken to ensure that the natural life of the environment is conserved and that rare species are not rendered extinct by over-zealous collecting.

This particular example of a more general danger led the Association to consider the topic of the conservation of the wild life of England and Wales, Capt. C. Diver describing the proposals of the Wild Life Conservation Special Committee. These include the setting aside of certain parts of Britain as Nature reserves and the starting of a State biological advisory service. A specific instance of the way in which properly trained biologists could act to ensure efficient public services and economy of public money was given by Prof. E. A. Spaul, of the University of Leeds, who described some of the work done by zoologists there on the biology of sewage and sewage disposal, much of which has been shown to depend upon the animal population of the filters. Mr. R. S. R. Fitter gave some examples of the type of problem—bird migrations, liberation of populations of known genetic constitution—to which answers might be found by the use of the special category of experimental Nature reserves which are also proposed.

NATURAL SELECTION OF *DROSOPHILA*

RECENT studies on wild populations of *Drosophila* are shedding considerable light on the effects of natural selection. By means of the cytological examination of salivary gland chromosomes, it is possible to analyse the nuclear constitution more precisely than in other living forms. For example, an inversion of part of a chromosome *abcde* to form a different chromosome *adcbe* is not infrequent, and may be quickly detected in the hybrid between two *Drosophila* containing these respective chromosomes. Generally there is no apparent difference in the characters of the individuals carrying normal or inverted chromosome arrangements. Occasionally, however, a large position effect is noted such as in 'roughoid' (Gruneberg, 1939).

Dobzhansky[1] and Dubinin and Tiniakov[2] have shown that the proportion of individuals carrying an inversion alters with time and place in wild populations of *D. funebris* and in *D. pseudoobscura*. For example, Dubinin and Tiniakov show that the proportions of individuals of *D. funebris* with inversions is lower in urban than in rural districts, and that under the intense natural selection of winter conditions the inversions II1, II2 and II4 were greatly reduced in proportion, whereas the inversion IV1 increased slightly. On the other hand, these inversions increased rapidly in proportion during the summer up to a maximum when the population was at its prime.

Similarly, Dobzhansky has shown that cyclic changes with the seasons took place in a wild population of *D. pseudoobscura* at Pinon Flats, California. These changes were on the whole constant during the years 1939–46. There was no trend towards one particular chromosome arrangement, although the proportions in the population were significantly different at different times of each year. This evidence becomes more significant when it is found that the same chromosome arrangements do show a definite trend at Keens Colony, which is 15 miles from Pinon Flats. During the years 1939–46 the standard arrangement increased in the population from 30 to 50 per cent, whereas the 'Arrowhead' arrangement decreased from 30 to 15 per cent. In all these cases no detectable difference in the morphology or physiology of the animals with different chromosomes has been observed.

In *D. pseudoobscura* the inversion heterozygotes are adaptively favoured in comparison with both the homozygotes; but in *D. funebris* there appears to be no difference between the inversion homozygote and the inversion heterozygote in respect of survival value. In each of the above cases either one simple or one compound rearrangement is present on one chromosome; it is expected and found that there is a consequent instability and increased plasticity of the population.

Recently a constant breeding population of *D. funebris* consisting entirely of individuals heterozygous for three inversions on chromosome 5 has been found near Manchester by Berrie and Sansome[3]. The three inversions are evenly placed on the chromosome, and no homozygotes have as yet been obtained among the forty individuals caught, or in their progeny. A multiple, probably successive, series of chromosome arrangements had occurred and a highly stable heterozygous system was the result. Obviously, the creation of such a system must be fortuitous, at least in respect of the occurrence of the inversions; but natural selection could control the trend of the subsequent evolution. F. W. SANSOME

ORIBATID MITES AND THEIR ECONOMIC IMPORTANCE

By M. ANANTARAMAN
Madras Veterinary College

REVIEWING some of the literature on Tyroglyphid mites, Lapage[1] directed attention to their role in pulmonary acariasis of man, in addition to destruction of stored food-products. The Oribatids are allied to these cheese- and flour-mites and to the well-known harvest- and chigger-mites, and have been, until a few years ago, of comparatively little economic significance. Otherwise known as moss-mites and beetle-mites, they have been studied for many years and from all over the world. They are mostly microscopic in size, free-living and terrestrial, although a few are aquatic and crawl on weeds. Their activity is greater in darkness, when they swarm out in search of food, and progression is normally slow. They have a shiny chitinous body-wall, a wing-like extension (the pteromorpha) at the antero-lateral corner of the abdomen on each side, a pair of peculiarly shaped sense-organs (the pseudo-stigmatic organs), and no eyes.

By and large denizens of the soil, the oribatid mites occur in decaying vegetation, among fungal mycelia, moss or algæ, and form a conspicuous group amid the soil biota. Some are confined to the soil and migrate on blades of grass during the night; others conceal themselves in the bark of trees or crawl on twigs and leaves. Depending upon their habitat, they are classified as terricolous, dendricolous, bryobious and humicolous.

In the group Acarina, which comprises parasites (Ixodoidea and Sarcoptidæ), predators (Trombidiidæ), and suckers of plant sap (Tetranychidæ), the Oribatoidea are outstanding in being herbivorous or saprophagous. They feed on moulds (fungivorous), algæ, decaying leaves or animal matter, and are distinctly inoffensive. Consequently, although systematists like Banks, Berlese, Nicolet, Michael, Oudemans, Jacot, Grandjean and Ewing have revealed the abundant and ubiquitous occurrence of these organisms, very few investigators attributed any importance to them. Michael[2], in his monograph, has remarked that none of the species is "injurious to man or his works". Jacot[3] regarded them, as "negative, humble and devoid of weapons of offense"; afterwards[4], he commented on the occurrence of *Damæosoma alces*, *Protoschelobates pembertoni* and *Xylobates pembertoni* in holes in cane roots, of *Lohmannia insignis* on bean seedlings and of *L. insignis dissimilis* on tulip bulbs as having no significance, because no evidence could be adduced that the holes were caused by the mites. He concluded that "the case against oribatides as non-injurious is becoming weightier".

Stunkard's[5] experiments on the development of *Moniezia expansa* disclosed the identity of the intermediate host of this tapeworm. He announced that *Zetes* (*Galumna*) *emarginatus* harboured the cysticercoids of the worm to the infective stage, and this discovery heralded a series of publications on the life-cycles of other Anoplocephalid cestodes. The work of Krull[6] (U.S.A.) on *Cittotænia* and *Moniezia*, of Stunkard[7] (U.S.A.) on *Bertiella studeri*, of Pullar[8] (Australia) on *Moniezia*, of Bashkirova[9] (U.S.S.R.) on *Anoplocephala* spp., and *Paranoplocephala mamillana*, of Potemkina[10] (U.S.S.R.) on *Thysaniezia ovilla*, and of the present writer[11] (India) on *Moniezia expansa* and *M. benedeni*, has involved oribatid mites of various genera and species as the undoubted vectors of these worms. Moreover, the same species of mite is observed to be capable of conveying more than one species of the cestode in a locality.

The Anoplocephalid tapeworms, characteristically devoid of rostellar hooks, are among the worst enemies of livestock, and to the veterinary parasitologist the oribatid mite has therefore suddenly become of major importance.

THE MESON FIELD AND THE EQUATION OF MOTION OF A SPINNING PARTICLE

By R. C. MAJUMDAR and DR. S. GUPTA
Tata Institute of Fundamental Research, Bombay

THE outstanding difficulty in obtaining the equation of motion of a spinning particle in a meson field which will take account of the reaction of the emitted meson field and is free from singularities is well known. The equation of motion was first obtained by Heisenberg[1] for a dipole of finite extension and is therefore not relativistically invariant. The relativistically invariant equations of motion for a point dipole which have been developed by Bhabha and Corben[2] and by Bhabha[3] are extremely complicated and involve a number of arbitrary constants which are not determined uniquely. These equations in their final form are free from singularities, and have been proved to involve only the contribution of the so-called radiation field, defined as half the retarded minus the advanced field, which is finite on the world line. However, the equations are established by proving that the singular terms are perfect differentials and can therefore be subtracted away.

In 1939, Riesz[4] developed an elegant method for solving the differential equations of hyperbolic type in which the divergent difficulties are avoided by a process of analytical continuation. The method has been recently applied by Fremberg[5] to obtain the classical equation of motion of a charged particle in an electromagnetic as well as in a meson field. Following Riesz, we shall define the potential and the field of a dipole for a parameter $\alpha > 2$ and show that the analytical continuation to $\alpha = 2$ gives the classical values corresponding to those of Lienard–Wiechert outside the world line, and a finite value on the world line itself giving the reaction of the field. The equations of motion of a point dipole can then be obtained in a straightforward way from the usual equation of a dipole as given by Frenkel[6]. The equations are free from singularities and do not contain any arbitrary constant except the spin angular momentum of the dipole.

We define the Riesz potential for the dipole at a point $P(\mathbf{x})$ outside the world line in the form,

$$\varphi_\nu^\alpha(P) =$$

$$\frac{g_2\chi^{4-\alpha}}{2^{\frac{1}{2}(\alpha-2)}\,\Gamma(\alpha/2)}\,\frac{\partial}{\partial x_\mu}\int_{-\infty}^{\tau_0} S_{\mu\nu}(\tau)\,(\chi s)^{\frac{1}{2}(\alpha-4)}\,J_{\frac{1}{2}(\alpha-4)}(\chi s)\,d\tau, \tag{1}$$

where τ is the proper time of the particle, τ_0 the retarded point of P, $J_n(x)$ is the Bessel function of order n and $g_2S_{\mu\nu}$ is the antisymmetrical tensor describing the dipole moment. The four-dimensional distance s is given by

$$s^2 = s_\mu s^\mu,\quad s_\mu = x_\mu - z_\mu. \tag{2}$$

The integral converges for $2 < \alpha < 5$. The potential (1) satisfies the wave equation of a dipole in a meson field given by

$$\frac{\partial}{\partial x_\rho}\frac{\partial}{\partial x^\rho}\varphi_\mu + \chi^2\varphi_\mu = 4\pi\frac{\partial}{\partial x_\nu}S_{\nu\mu}, \tag{3}$$

when we continue analytically to $\alpha = 2$.

Now it can be shown after some calculations that the analytical continuation to $\alpha = 2$ of the Riesz potential (1) and the corresponding field-strength for the dipole lead to the well-known Lienard - Wiechert results, as already obtained by Bhabha and Corben :

$$\varphi_\nu{}^2(P) = \varphi_\nu{}^{\text{ret}} = g_2 \left[\frac{1}{\varkappa}\frac{d}{d\tau}\left(\frac{s^\mu S_{\mu\nu}}{\varkappa}\right)\right]_0 - \frac{g_2\chi^2}{2}\left[\frac{s^\mu S_{\mu\nu}}{\varkappa}\right]_0 + g_2\chi^2 \int_{-\infty}^{\tau_0} \frac{s^\mu S_{\mu\nu}}{s^2} J_2(\chi s)d\tau, \quad (4)$$

$$F_{\mu\nu}{}^2(P) = F_{\mu\nu}{}^{\text{ret}} = g_2\left[\frac{1}{\varkappa}\frac{d}{d\tau}\left(\frac{S_{\mu\nu}}{\varkappa}\right)\right]_0 + g_2\left[\frac{1}{\varkappa}\frac{d}{d\tau}\left(\frac{1}{\varkappa}\frac{d}{d\tau}\left(\frac{T_{\mu\nu}}{\varkappa}\right)\right)\right]_0 - \frac{g_2\chi^2}{2}\left[\frac{S_{\mu\nu}}{\varkappa}\right]_0 - \frac{g_2\chi^2}{2}\left[\frac{1}{\varkappa}\frac{dT_{\mu\nu}}{d\tau}\right]_0 + \frac{g_2\chi^4}{8}\left[\frac{T_{\mu\nu}}{\varkappa}\right]_0 + g_2\chi^2\int_{-\infty}^{\tau_0}\frac{S_{\mu\nu}J_2(\chi s)}{s^2}d\tau - g_2\chi^3\int_{-\infty}^{\tau_0}\frac{T_{\mu\nu}J_3(\chi s)}{s^3}d\tau - \text{the same}$$

terms with μ and ν interchanged, ... (5)

where $\varkappa = s_\mu v^\mu$, $T_{\mu\nu} = s_\mu s^\sigma S_{\sigma\nu}$. The suffix 0 implies that the value of the function is to be taken at the retarded point of P.

In order to calculate the potentials and the fields at a point P on the world line, we divide the integrals into two parts, one in the interval $-\infty$ to $\tau_0 - \varepsilon$, and the other from $\tau_0 - \varepsilon$ to τ_0. It is easily seen that the first integral vanishes for $\alpha = 2$. We then expand the quantities in the second integral in power series of τ, measured from τ_0 taken as zero, and obtain by analytical continuation to $\alpha = 2$ the following expressions :

$\varphi_\nu{}^{\alpha=2}$ (on the world line) =

$$- g_2\left[\frac{1}{3}\ddot{v}^\mu S_{\mu\nu} - \frac{1}{3}v^\mu S_{\mu\nu}(v\ddot{v}) + \dot{v}^\mu \dot{S}_{\mu\nu} + v^\mu \ddot{S}_{\mu\nu}\right] - \frac{1}{2}g_2\chi^2 v^\mu S_{\mu\nu} + g_2\chi^2\int_{-\infty}^{\tau_0} s^\mu S_{\mu\nu}\frac{J_2(\chi s)}{s^2}d\tau, \quad (6)$$

$F_{\mu\nu}{}^{\alpha=2}$ (on the world line) =

$$g_2\Bigg[\frac{2}{3}S_{\mu\nu}(\dot{v}\ddot{v}) + \frac{2}{3}\dot{S}_{\mu\nu}\dot{v}^2 + \frac{2}{3}\dddot{S}_{\mu\nu} - \Big\{\frac{4}{3}v_\mu S_\nu{}''' + 2v_\mu S_\nu{}'\dot{v}^2 + \frac{1}{3}\dddot{v}_\mu \$_\nu + \frac{2}{3}\ddot{v}_\mu\dot{v}^\sigma S_{\sigma\nu} + \frac{4}{3}\ddot{v}_\mu S_\nu{}' + \frac{4}{3}v_\mu\ddot{v}^\sigma\dot{S}_{\sigma\nu} + \frac{2}{3}\dot{v}_\mu\ddot{v}^\sigma S_{\sigma\nu} + \frac{1}{3}v_\mu\dddot{v}^\sigma S_{\sigma\nu} + 2v_\mu\dot{v}^\sigma\ddot{S}_{\sigma\nu} + 2\dot{v}_\mu S_\nu{}'' + 2\dot{v}_\mu\dot{v}^\sigma\dot{S}_{\sigma\nu} + 2v_\mu\$_\nu(\dot{v}\ddot{v}) + v_\mu\dot{v}^\sigma S_{\sigma\nu}\dot{v}^2 + \dot{v}_\mu\$_\nu\dot{v}^2\Big\}_- + \chi^2\Big\{\dot{S}_{\mu\nu} - [v_\mu S_\nu{}']_- - \frac{1}{2}[v_\mu\dot{v}^\sigma S_{\sigma\nu}]_- - \frac{1}{2}[\dot{v}_\mu\$_\nu]_-\Big\}\Bigg] + 2g_2\chi^2\int_{-\infty}^{\tau_0} S_{\mu\nu}\frac{J_2(\chi s)}{s^2}d\tau - g_2\chi^3\int_{-\infty}^{\tau_0}[s_\mu s^\sigma S_{\sigma\nu}]_-\frac{J_3(\chi s)}{s^3}d\tau, \quad \ldots \quad (7)$$

where

$$\$_\nu = v^\sigma S_{\sigma\nu},\ S_\nu{}' = v^\sigma\dot{S}_{\sigma\nu},\ S_\nu{}'' = v^\sigma\ddot{S}_{\sigma\nu},\ S_\nu{}''' = v^\sigma\dddot{S}_{\sigma\nu}, \quad (8)$$

and the minus sign as subscript denotes that the terms inside the brackets are to be subtracted with interchange of μ and ν.

It is to be noticed that the field given by (7) is, in fact, the retarded field, and agrees with the so-called radiation field of Dirac as obtained by Bhabha and Corben, provided we put $k_1 = -1/3$, $k_2 = -7/15$, $k_3 = 1/3$, $k_4 = 4/3$, $k_6 = 0$ in (140) (Bhabha and Corben) and $k = 2$ in (110) (Bhabha). There is, however, disagreement in terms with constant k_5, which has also been noticed by Harish-Chandra[7], whose calculations of the radiation field on the world line by retaining the finite and the unambiguous terms of the fields agrees with our result (7).

The equation of motion is now obtained from Frenkel's equation

$$I\,\dot{S}_{\mu\nu} = g_2[S.F^{\text{ext}}]_{\mu\nu} + g_2[S.F^{\text{react}}]_{\mu\nu}, \quad (9)$$

where I is the spin angular momentum. The field $F_{\mu\nu}$ in the second term of the right-hand side is given by (7) above. The equation of motion of a point dipole in a scalar meson field is also similarly obtained.

The detailed paper will be published in due course in the *Physical Review*.

Royal Institute of Chemistry, London and South-Eastern Counties Section (joint meeting with the Dartford Branch of the Pharmaceutical Society, at the County Technical College, Essex Road, Dartford), at 7.15 p.m.—Dr. A. Albert : "Physico-Chemical Concepts in Interpreting Drug Action".

Tuesday, March 16

British Psychological Society, Industrial Section (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 1 p.m.—Annual General Meeting ; Mr. Dermot Straker : "The Importance of Information in Vocational Selection".

Chadwick Public Lecture (in the Sir Edward Meyerstein Lecture Theatre, Westminster Hospital Medical School, 17 Horseferry Road, London, S.W.1), at 2.30 p.m.—Dr. J. R. Nicholls : "Adulteration of Food and its Detection".*

Royal Society of Arts, Dominions and Colonies Section (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Dr. E. Marsden, F.R.S. : "Co-ordination of Research in the Pacific".

Linnean Society of London (joint meeting with the Systematics Association, at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Discussion on "The Organization of Taxonomic Research".

Royal Anthropological Institute (at 21 Bedford Square, London, W.C.1), at 5 p.m.—Miss Laura E. Start : "Indian Textiles from Guatemala and Southern Mexico".

Royal Statistical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5.15 p.m.—Mr. F. J. Anscombe : "The Validity of Comparative Experiments".

Eugenics Society (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Dr. W. Mayer Gross : "Mental Health Survey in a Rural Population".*

Conway Discussion Circle (at Conway Hall, Red Lion Square, London, W.C.1), at 7 p.m.—Dr. W. E. Swinton : "The Rise and Fall of the Dinosaurs".*

Institution of the Rubber Industry (at Caxton Hall, Caxton Street, London, S.W.1).—Dr. D. A. Harper : "The Technology of some New Condensation Rubbers".

Tuesday, March 16—Thursday, March 18

Institute of Metals (at the Institution of Civil Engineers, Great George Street, London, S.W.1).—Annual General Meeting.

Wednesday, March 17

Society of Chemical Industry, Food Group (joint meeting with the Midland Section of the Society of Dairy Technology, at the Technical College, Wolverhampton), at 2.15 p.m.—Discussion on "The Chemical Sterilization of Food Plant" (to be opened by Dr. E. B. Hughes and Mr. J. C. L. Resuggan).

Royal Institute of Chemistry, London and South-Eastern Counties Section (joint meeting with the London Branch of the Institute of Physics, at the Royal Institution, Albemarle Street, London, W.1), at 2.30 p.m.—Dr. A. E. Alexander: "Emulsions and Emulsification".

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Prof. H. G. Champion: "Re-afforestation as a World Problem".

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 3 p.m.—Annual General Meeting; Prof. H. H. Read, F.R.S.: "Place in Plutonism" (Presidential Address).

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Discussion on "Atmospheric Turbulence".

Royal Microscopical Society (at B.M.A. House, Tavistock Square, London, W.C.1), at 5.30 p.m.—Dr. R. J. Ludford: "Application of the Barnard Ultra-Violet Light Technique for the Study of Living Cells"; Mr. J. Smiles: "New Development in Visual Light Microscopy".

British Institution of Radio Engineers, Scottish Section (at the Heriot Watt College, Edinburgh), at 6.30 p.m.—Dr. Angus Campbell: "The Development of Radiology".

Manchester Metallurgical Society (at the Engineers' Club, Albert Square, Manchester), at 6.30 p.m.—Annual General Meeting; Mr. R. S. Brown: "Modern Heat Treatment Furnaces".

Society for Visiting Scientists (at 5 Old Burlington Street, London, W.1), at 7.30 p.m.—Discussion on "The Growing Points in Science", 3. (To be opened by Prof. O.R. Frisch and Dr. K. Weissenberg.)

Institution of Naval Architects (at 10 Upper Belgrave Street, London, S.W.1).—Annual General Meeting.

Wednesday, March 17—Friday, March 19

Institution of Naval Architects (at the Royal United Services Institution, Whitehall, London, S.W.1).—Eighty-ninth Annual Meetings.

Thursday, March 18

Chemical Society (in the Lecture Theatre, Physical Chemistry Laboratory, South Parks Road, Oxford), at 12 noon.—107th Annual General Meeting; at 3 p.m.—Prof. C. N. Hinshelwood, F.R.S.: "Some Aspects of the Chemistry of Hydrocarbons" (Presidential Address).

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. J. D. Griffith Davies: "John Wilkins and the Royal Society" (The Wilkins Lecture).

Institution of Mining and Metallurgy (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. H. R. Potts: "Further Notes on Converter Practice at Rio Tinto".

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. G. Birkhoff: "Lattice Theory and its Applications".

British Glaciological Society (at the Royal Geographical Society, Kensington Gore, London, S.W.7), at 5.15 p.m.—Dr. A. Farrington: "The Glacial Drifts of the Leinster Chain".

Illuminating Engineering Society, Manchester Centre (in the Reynolds Hall, College of Technology, Manchester), at 6 p.m.—Mr. T. S. Jones: "School Lighting".

Royal Aeronautical Society (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 6 p.m.—Mr. H. Davies: "Flight Testing at High Subsonic Speeds".

Oil and Colour Chemists' Association, London Section (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Dr. L. Ivanovsky and Dr. A. C. Healey: "The Uses of Greases and Waxes in Printing Ink and Related Materials".*

Royal Photographic Society, Scientific and Technical Group (at 16 Prince's Gate, London, S.W.7), at 7 p.m.—Symposium on "Photography in Nuclear Research".

Friday, March 19

Physical Society, Colour Group (in the Small Physics Lecture Theatre, Imperial College of Science, Imperial Institute Road, London, S.W.7), at 3.45 p.m.—Eighth Annual General Meeting; Mr. J. G. Holmes: "The Aims and Activities of the Colour Group"; at 5 p.m.—Mr. J. G. Holmes: "The Physical Structure of Coloured Glass".

Institution of Electrical Engineers (joint meeting of the Measurements and Transmission Sections, at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. E. W. Connon and Mr. E. Smith: "The Influence of Inverse Time-Relay Characteristics on Discriminative Time".

Institution of Mechanical Engineers (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Annual General Meeting.

North-East Coast Institution of Engineers and Shipbuilders (at the Mining Institute, Newcastle-upon-Tyne), at 6.15 p.m.—Mr. Arnold Emerson and Mr. N. A. Witney: "Experiment Work on Merchant Ship Models during the War".

British Institution of Radio Engineers, Midland Section (at the Technical College, The Butts, Coventry), at 6.30 p.m.—Mr. N. E. Head: "Methods of Measuring Insertion Loss, Phase Shift and Time Delay of Transmission Networks".

*Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Sir Lawrence Bragg, F.R.S.: "Metal Physics".

Friday, March 19—Saturday, March 20

British Rheologists' Club (joint meeting with the Textile Institute, the Society of Dyers and Colourists, the Leeds Area Local Sections of the Chemical Society and the Royal Institute of Chemistry, the Yorkshire Section of the Society of Chemical Industry, and the Manchester and District Branch of the Institute of Physics, in the Department of Textile Industries, The University, Leeds).—Conference on "Rheology in the Textile Industries".

Saturday, March 20

Amateur Entomologists' Society (at Buckingham Gate Central School, Wilfred Street, London, S.W.1), at 2 p.m.—Entomological Exhibition.*

Institution of Chemical Engineers, North-Western Branch (in the Reynolds Hall, College of Technology, Manchester), at 3 p.m.—Mr. N. T. Gridgeman: "Value of Statistics to the Chemical Engineer".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Scientist, Grade I (with good honours degree in science or an equivalent qualification)—The Administrative Officer, National Coal Board, Northern Division, Scientific Department, The Grange, Longbenton, Newcastle-upon-Tyne (March 20).

Laboratory Steward for the Department of Zoology—The Clerk, Birkbeck College, Breams Buildings, London, E.C.4 (March 22).

Research Assistant in the Professorial Unit—The Secretary, Royal Eye Hospital, St. George's Circus, London, S.E.1 (March 22).

Assistant Lecturer in Horticulture, an Assistant Lecturer in Poultry Husbandry, and an Assistant Lecturer in Rural Domestic Economy, including Dairy Husbandry, at the Essex Institute of Agriculture, Writtle—The Chief Education Officer, County Offices, Chelmsford (March 23).

Assistant (male) in the Technical and Advisory Section to assist in putting over the work in progress to scientists, fruit-growers, and the general public—The Secretary, East Malling Research Station, East Malling, Maidstone, Kent (March 27).

Lecturer (Grade II or Grade III) in Electrical Engineering—The Secretary and Registrar, The University, Bristol (March 27).

Lecturer in Theoretical Chemistry, a Lecturer in Pure Mathematics, and a Lecturer in Zoology—The Secretary, The University, 38 North Bailey, Durham (March 27).

Senior Stressmen (2), a Radio and Electrical Engineer, and Senior Draughtsmen (2), for work in Australia on the design of small high-speed, jet-propelled aircraft—The Deputy High Commissioner, Australia House, Strand, London, W.C.2 (March 31).

I.C.I. Research Fellowships in biochemistry, chemistry, engineering, pharmacology or physics—The Secretary of University Court, The University, Glasgow (March 31).

Lecturer and Assistant Lecturer in Statistics with experience in the application of statistical methods in the social sciences—The Secretary, London School of Economics, Houghton Street, Aldwych, London, W.C.2 (March 31).

Demonstrator in each of the Departments of Physics, Chemistry, Botany and Zoology, at the University College of the West Indies, Jamaica—The Secretary, Inter-University Council for Higher Education in the Colonies, 8 Park Street, London, W.1 (April 1).

Lecturer (Grade III) in the Department of Geography—The Clerk, Birkbeck College, Breams Buildings, London, E.C.4 (April 3).

Senior Assistants (one in Bacteriology and one in Pathology), and a Senior Lecturer in Physiology, in the University of Cape Town—The Secretary, Universities Bureau of the British Empire, 8 Park Street, London, W.1 (April 5).

Second Assistant at the Bolus Herbarium, University of Cape Town—The Secretary, Universities Bureau of the British Empire, 8 Park Street, London, W.1 (April 5).

Chair of Psychiatry—The Registrar, The University, Manchester 13 (April 9).

Research Fellowship in Science—The Secretary, The University, 38 North Bailey, Durham (April 10).

Assistant Director, Engineering Class, in the Ministry of Supply—The Secretary, Civil Service Commission, Scientific Branch, 27 Grosvenor Square, London, W.1, quoting No. 2132 (April 12).

Professor of Chemistry—The Registrar, University College, Singleton Park, Swansea (April 17).

Lecturer or Assistant Lecturer in the Department of Physics, and a Lecturer or Assistant Lecturer in Psychology to work under the Professor of Philosophy—The Registrar, The University, Sheffield (April 24).

Lecturer (Grade II or Grade III) in Statistics, and an Assistant Lecturer (Grade III) in Applied Mathematics—The Registrar, The University, Liverpool (May 15).

Chair of Electrical Engineering—The Secretary, Royal Technical College, Glasgow.

Assistant Serologist—The Secretary, Wright-Fleming Institute of Microbiology, St. Mary's Hospital, Paddington, London, W.2.

Physicist to the Radiotherapy Centre—The House Governor, Hull Royal Infirmary, Hull.

Physicist to investigate, in collaboration with senior rheologist, physical properties of bovine secretion—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, Berks.

Lecture Assistant in the Department of Chemistry—The Registrar, University College, Singleton Park, Swansea.

Assistant Editor of "Science Abstracts" to select and edit abstracts for "Physics Abstracts"—The Secretary, Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2.

Junior Chemists (2, in Derby and London respectively)—The Scientific Research Manager, Railway Executive (London Midland Region), Euston Station, London, N.W.1.

THE EUROPEAN TRADITION OF FREEDOM

As the Marshall Plan for Europe takes shape, the question of the future design of Western Europe grows more acute and urgent. No longer is it possible to avoid the challenge which this Plan, and also the course of events in Eastern Europe, are throwing down to those nations of Western Europe which recognize the value of the European tradition of freedom. We have indeed to consider as a matter of urgency whether the United Nations is not already an inadequate instrument in view of the breach between east and west in Europe, and whether it can yet be modified or strengthened to serve the purposes for which it was designed; or whether on the other hand we must seek other means of securing peace and upholding the freedom and great cultural and spiritual values which we have inherited in the civilization of Western Europe.

It is to this problem that Sir Harold Butler addressed himself in his book "Peace or Power" before the Marshall Plan was announced, and it is also the theme of publications issued by the Design for Freedom Committee[*], which appeared later. One of them, "Design for Europe", urges that the ideal of world unification which has steadily developed through the past century should be given effect so far as possible by the free nations of the world, and that new machinery should be developed for this purpose by all those nations which are willing to co-operate in giving effect to the ideals of world government.

There can be no accommodation between the ideas of the liberty of man and the slave State, and accordingly the Design for Freedom Committee concludes that the ideal of a single world organisation is at present impossible. Proceeding to analyse the alternatives, it is urged that the only real obstacles to world unity which exist to-day lie in the realm of thought; within the ranks of those who demand human liberty there is no justification for the erection of artificial distinctions and divisions, in the economic, cultural or political spheres. It is suggested that the free world includes all those countries in which Roosevelt's Four Freedoms are regarded as good and desirable; the British Empire, the United States, France, part of Latin America, the Scandinavian countries, Holland, Belgium and Luxembourg, resurgent Italy and Switzerland. Greece is a battlefield where the issue is still at stake. But as a first step, it is urged that a Monnet Plan is required for Europe as a whole, and this as a first condition of giving effect to the Marshall proposals by freeing European trade.

It is suggested that those countries which wish to benefit from American financial help should without delay accept the general principles of the "Proposals for an International Trade Organisation", although the European Plan itself may constitute the special circumstances which provide justification for new preferential arrangements requiring an exception to the provisions of the agreement. Next, those countries must undertake that, as a condition of participation, they will not raise their tariffs or impose quotas on some particular range of goods. The Plan should also provide for some form of free trade over European waterways and railways, at least for the right of passage of goods in bond across one country to their destination. Some super-national administration will be necessary for the funds made available by the United States, involving limitation of sovereignty to the extent of seeing that the conditions are enforced. Although this is economic in intent, its consequences are bound to be political, and something beyond the administration contemplated in the European Recovery Programme proposed to Congress by President Truman on December 19 may therefore well be required.

---

[*] "Design for Europe." Pp. 24. "The New Courageous." By John Maude. Pp. 16. (Design for Freedom Committee, 22 Chester Square, London.) 1s. each.

These conditions fall short of the United States of Europe urged by Mr. Churchill at Zurich in September 1946, though they are broadly in line with the actions which President Truman suggested in the recovery programme each country should pledge itself to take. That programme indeed goes further, suggesting pledges to increase industrial and agricultural production, to take the necessary measures to stabilize currency, establish or maintain a proper rate of exchange, make efficient use of the country's own resources, as well as of the goods and services made available through the United States aid, and stimulate the production of specified raw materials ; these undertakings are so plainly questions of self-interest to the country concerned that failure to give and to honour them is tantamount to a confession of bad faith. "Design for Europe" does not hesitate to touch bluntly on issues that have been kept rather in the background, and is a stimulus to the thinking that should be proceeding throughout Europe.

It is well that it should be remembered that domestic policy cannot be pursued without regard to its international implications ; policies which hinder the immediate creation of an international organisation in which the genuine confidence of all the nations of the free world can straightway be placed are dangerous and reactionary. No satisfactory economic plan for Europe can be devised without some sacrifice of sovereignty on the part of the nations concerned, nor can we expect others to make this sacrifice if we are not equally prepared to do so. The same condition applies to that close association of the British Commonwealth and the United States of America for which the Design for Freedom Committee believes the condition of the world calls. Recognition of this need is at least as important as the attempt now being made to obtain a degree of unity in Europe, for any scheme of European unification will eventually break down if it is not underwritten by joint Anglo-American action.

Here then we find the value of a further Design for Freedom publication, "The New Courageous", by John Maude. In it the emphasis is laid on the things that government cannot provide, and the challenge to the moral qualities of the ordinary citizen that the situation offers. Not merely harder work and lower standards of living are demanded of us, but also higher standards of co-operation and friendship between all men. The wisest and most courageous leadership cannot supply the things of the spirit upon which, above all, the happiness of a people depends ; it can only help to provide the conditions in which the individual citizen has the best chance to achieve the health, security and leisure out of which his own exertions can build a full and satisfying life.

Mr. Maude rightly stresses the need for leadership, local as well as national ; but his pamphlet is above all a call to face the fact that recovery will be arduous in the extreme and will require personal sustained exertion and the moral qualities which can make a people great. It is these same moral qualities which provide the firm basis of Anglo-American unity as much as of European unity, whether in the form immediately presented to us, or ultimately in the United Nations Organisation, or the Federal World suggested by Clarence Streit. These ideals may be remote, but they are not impossible if we match them with the courage and vision which illuminate the Marshall Plan, and refuse to allow narrow interests to stand in the way of a new approach to Europe's needs.

Although it is different in scale and scarcely reaches the nobler plane of his earlier work "The Lost Peace", Sir Harold Butler's recent "Peace or Power"* reflects much the same spirit. The larger part of the book reviews briefly but incisively the course of events from the armistice of 1918 to the outbreak of war in 1939, and then the trend of events in Europe since the German surrender. Sir Harold is at pains to discern the real causes of the conflict between east and west ; and, like the Design for Freedom Committee, he finds it has deeper historical roots than just a clash between communism and democracy. It is a clash between the free ideals of Western civilization and the authoritarian ideals of the East.

Sir Harold argues that the way to perfection cannot be through hatred, intolerance, injustice, tyranny and misery, by whatever names they may be disguised, or by whatever sophistry they may be excused. But the suggestion that the conflict between democracy and communism is not so much an affair of ends as of means is open to question. All the evidence at present goes to show that the police State is poles apart from the Four Freedoms and the whole tradition of Western civilization of which Sir Harold himself is no mean exponent. His discussion of recent changes in Central European and Slav countries scarcely maintains the level of his chapters on "The German Reckoning", "The British Price for Victory" or "The American Impact". Although he rightly stresses the dominant importance of the agrarian problem, his treatment of Russia in Europe is sometimes superficial and tends to overlook the earlier contacts of Russia with Byzantium and with Europe through the Hanseatic league. None the less, on the vital issue he is unequivocal ; and although he recognizes that parliamentary democracy is fatally compromised in the greater part of Eastern Europe, he believes that Western democracy —the willing submission of the minority to the majority in the confidence that its submission will not be abused—provides the only approach to peace. In that, moreover, is involved a more positive and constructive conception of democracy such as is implicit in the Marshall offer and the European Recovery Programme put forward in the United States.

---

* Peace or Power. By Sir Harold Butler. Pp. 260. (London: Faber and Faber, Ltd., 1948.) 15s. net.

In the national democracies, survival depends upon the response of their citizens to the new conception of positive duties and to the ability to train men and women to accept and discharge those responsibilities of citizenship. So too, as Mr. Middleton Murry has pointed out, the survival of world-society depends upon an equally new conception of the positive duties of one nation to another in the economic sphere and in the maintenance of the world's peace. We may fairly claim that Britain has been a pioneer of positive domestic democracy; but we should also be prompt to recognize in the American offer to Europe that the United States is the pioneer of positive international democracy, and to match her vision and generosity with vigorous, prompt and radical action. The challenge is, indeed, to wring from destiny a peace which only men of good will can achieve; and the success of that plan—the issue of peace or power—depends supremely on whether Britain and Europe can find the men of good will.

One need look no further than to the study by Mass-Observation entitled "Peace and the Public"* to realize how immense is the task of creating an informed and intelligent public opinion on international affairs, or the dangers inherent when a general intangible desire for peace is accompanied by ignorance of what is involved, and a disposition to lay the responsibility for action on others.

The question of peace or power is fundamentally one of men, of values and of positive measures, and as such it touches the man of science closely. Leaving on one side the implications and the urgency which the advent of nuclear energy and atomic warfare has brought to the situation, in the conception of positive democracy he has already played a large part, as Dr. Julian Huxley has shown in his little book "Democracy Marches" and later in "T.V.A.—Adventure in Planning". Moreover, if, as Dr. Huxley emphasizes, freedom of speech, of opinion, of discussion, of belief, and of research are vital to a democratic society, the man of science must accept some responsibility for safeguarding them. In General Smuts' words, "Europe has been the spiritual home of the west, the source of our concepts of progress, liberty and all the other basic ideas of our higher life . . . Europe is the heart of the cause of man, and her decadence would mean an immeasurable loss to all that is most precious in the human heritage". None the less, the challenge of Soviet Russia to the civic and personal liberties at stake all over Europe must be met by positive achievement, by the proof that the great traditions of the past—the heritage of freedom—can supply the mainspring for fresh advances, creative thought and the effective service of the changing needs of man. That, too, depends on the co-operation of the man of science. Whatever he can do to spread more widely the scientific outlook and an appreciation of what is implied in the scientific method will fortify his fellow citizens against the dangers of propaganda.

DOCUMENTATION OF ORGANIC CHEMISTRY

Elsevier's Encyclopædia of Organic Chemistry
Edited by E. Josephy and F. Radt. Series 3: Carboisocyclic Condensed Compounds. Vol. 13: Tricyclic Compounds. Pp. xx + 1265. (New York and Amsterdam: Elsevier Publishing Co., Inc.; London: Cleaver-Hume Press, Ltd., 1946.) £25 17*s*.; to Subscribers to Series 3, £22 2*s*.; to Subscribers to Whole Work, £19 7*s*.

LIKE most other sections of the community, organic chemists have their peculiar worries. One perpetual cause for concern is the increasing difficulty of finding, in easily accessible form, complete and up-to-date information about results of research on individual compounds or in particular fields. The older original literature is well indexed and fully summarized, but the task of compiling the standard indexes and reference works has not kept pace with the accumulation of new knowledge. Publication of the fourth edition of Beilstein's "Handbuch der organischen Chemie" began at about the same time as the reviewer's chemical career—that is, more than a quarter of a century ago. With its first supplement, this fourth edition completes the survey of the organic chemical literature only up to the end of 1919. Several volumes of the second supplement have been published, and if all goes well with plans now being made this supplement will be complete in 1952. By then, therefore, the literature up to the end of 1929 will have been covered; but the advances of the intervening twenty-three years will have no adequate and comprehensive summary.

It is against this background that Elsevier's "Encyclopædia of Organic Chemistry" must be regarded, for there is no doubt that it is intended as a serious competitor to "Beilstein", and that it claims superiority to "Beilstein" in certain important respects. The "Elsevier" scheme provides for the issue of twenty volumes of the main work, which is arranged as four series. Vol. 14, the first to be issued, has already been noticed in these columns (*Nature*, 160, 626; 1947); it deals with tetra- and higher-cyclic compounds. The volume now under review is concerned with tricyclic compounds; it is to be followed shortly by vol. 12 (bicyclic compounds), subdivided into 12*A* (excluding naphthalene) and 12*B* (naphthalene compounds). Vols. 12, 13 and 14 together comprise Series 3 of the whole work (Carboisocyclic Condensed Compounds). Other volumes besides 12 are apparently to be subdivided, as it is stated that the entire work will consist of approximately thirty-eight parts. The price of the complete work will place it beyond the reach of individuals, and it is clearly intended for libraries and research institutes. But the arrangement of material is such that each volume is largely self-contained, and many organic chemists (and even physical chemists) will wish to obtain for their own bookshelves selected volumes or perhaps a series. The present volume, dealing *inter alia* with fluorene, acenaphthene, anthracene, phenanthrene and their derivatives, will be invaluable to those with a special interest in compounds of these classes. The largest section, dealing with anthracene and its derivatives, comprises 590 pages, excluding indexes, and is a treatise in itself. It contains an excellent modern survey of the bibliography of anthracene and anthraquinone, and their derivatives.

Future parts of the "Encyclopædia" are scheduled to appear at six-monthly intervals, and the plan provides for the completion of the whole work by 1963. Each volume is to include all the original literature of the compounds within its purview, up to four years prior to its date of appearance. Supplements are also to be issued, each ten years after the respective part of the main edition.

This is an ambitious scheme and a formidable undertaking, about which many searching questions will be asked. Will it be possible to adhere to the proposed time-schedule ? Does the system of classification facilitate rapid reference ? Is there justification for the publisher's claim that the "Encyclopædia" gives "complete information on all chemical and physical properties and on the most important physiological properties of organic compounds" ? Is the information absolutely reliable, and are the data accurately transcribed from the original memoirs ? How does the work compare with "Beilstein", and is there a need for both these works of reference ?

"Beilstein" is an established institution in organic chemistry, and has acquired great prestige and a tradition for comprehensiveness and reliability. It will not be lightly discarded in favour of some new and untried publication. "Beilstein" is not completely infallible ; but it is a rare and outstanding achievement to find an error. The chief defects are (*a*) the time-lag which causes much of the material to be nearly thirty years out of date, and (*b*) the cumbersome system of classification, which results in data on closely related compounds being scattered over the entire range of volumes, and makes it sometimes difficult to find the desired information.

It is pertinent to ask what are the prospects of the quality of "Beilstein" being maintained in the future and of reducing the period of induction before new knowledge is available in the "Handbuch". Prior to the War the indexing and preparation of material was carried on in Berlin in direct association with the German Chemical Society, which no longer exists. There was ample accommodation for the work and excellent facilities, especially in regard to the availability of periodicals. A few months ago the reviewer had the opportunity to see the present editorial office at Frankfurt-Hoechst, in the American Zone, and to renew acquaintance with Dr. Richter, the editor. Working conditions fall far short of those formerly enjoyed in Berlin, and if the project to complete the second supplement by 1952 is to succeed there will need to be great improvement in office accommodation, supply of periodicals, etc. Moreover, under present conditions in Germany supplies of paper and publishing facilities are by no means assured for a venture of this magnitude. The outlook is probably not so gloomy as these comments might suggest, as there are powerful and sympathetic interests at work in support of the "Beilstein" organisation, and there is reason for hoping that many current difficulties will be surmounted.

As regards the Elsevier "Encyclopædia", it would be premature to attempt now any final assessment of its completeness and its accuracy. This will be made by the many chemists who will use it during the coming years. At this stage one can give only first impressions from what has necessarily been a somewhat superficial survey. These impressions, as regards the volume under review as also in regard to vol. 14, have been wholly favourable. The reviewer had already had the opportunity of seeing, in 1939, the organisation set up in Amsterdam for the production of this "Encyclopædia", and of meeting the editors, Dr. Josephy and Dr. Radt, both of whom were formerly members of the "Beilstein" staff. Dr. Josephy was 'liquidated' by the Nazis during the occupation of Holland. Dr. Radt, who happily survived the War, had a considerable share in the composition of the first supplement of "Beilstein", and had been entrusted with the direction of the preparatory work for the second supplement. It was clear, therefore, that the preparation of the Elsevier "Encyclopædia" was in very experienced hands, and the extensive array of card indexes in the editorial office bore witness to the immense amount of work already put into the project by 1939.

Vol. 13 is an excellent production. It is admirably printed in clear type, and the text is liberally illustrated with structural formulæ. Throughout the main sections the left-hand page bears at the top the structural formula of the parent compound, with its numbering. Chronological lists of references are given at the end of each sub-section, and at the foot of each page is given, where necessary, the numbers of the pages on which the appropriate references are listed. Many users will find it inconvenient not to have the full reference on the same page as the description of the compound, but the system used probably saves space. Publication was delayed by the War, and the present volume, dated 1946, states that the literature up to and including 1936 has been consulted, and the literature concerning the structure of compounds up to 1947. Certainly the newer work seems to have been noted in cases where important revisions of structure have been made, and there are numerous references to publications of the period 1937–45.

In the preface to vol. 14 it is claimed that all the data from the 231 journals listed have been taken directly from the original journals. Presumably this claim applies also to the list of nearly 270 periodicals given in the present volume. Where abstracts only have been consulted the abstract references are given. The most important omission concerns patent specifications, to which reference is not made. This limits considerably the usefulness of the present volume to chemists who are interested in anthraquinone dyestuffs. Apart from this, the reviewer has looked in vain for errors or omissions. It is claimed that the "Encyclopædia" will list and describe all organic compounds reported in the scientific literature throughout the world. It is not claimed that all references to a particular compound will be mentioned in the entry relating to that compound, and, in fact, this has not been done. In some cases this may lead to confusion. For example, p. 712 gives a structure (in an obsolete form which appears to have been copied from "Beilstein") of 5-diazoanthraquinone-2-sulphonic acid. In the only paper cited in this entry the compound is described as the 1-diazo-2-sulphonic acid, an error which was corrected in a paper published five years later. The reference to the later paper, although it is given in a neighbouring entry in the "Encyclopædia", does not appear under that relating to the diazo compound, and without this reference there is nothing to show why the structure has been modified.

The presentation of the data has been done with great skill, and gives evidence of expert chemical knowledge and sure instinct. Thus, there are apt editorial comments concerning the possible origin of certain bands in the infra-red absorption spectrum recorded for phenanthrene (p. 789); on the structures of an ether of xanthopurpurin (p. 527), of the nitration product of 2-ethoxyanthracene (p. 279), and of an alleged hexahydroanthracene (p. 518). An attractive feature is the introduction of schemes of formulæ illustrating reactions of certain rather complex natural products such as abietic acid and some related compounds, cedrene, tricyclene and its derivatives, colchicine, thebaine and carminic acid (given as carmic acid); similar schemes show the reactions of the dicyclopentadienes. Extensive quotation of physical constants and references to papers dealing with biological effects of many of the substances will appeal to many users. Space is saved and reference facilitated by describing in tabular form the characteristics of numbers of closely related compounds; for example, the colours of the azo derivatives of anthraquinone-sulphonic acids, and the physical constants of the alkylphenanthraquinones and of the pharmacologically interesting phenanthrylaminoalkyl carbinols.

The arrangement adopted in the "Encyclopædia" aids rapid reference, and groups together hydrocarbons and their various functional derivatives. It has, nevertheless, certain disadvantages. Thus, there are references to tricyclic sesquiterpenes in two widely separated sections of the present volume, and other classes of sesquiterpenes will presumably be included in other volumes. Again, although the tetracyclic sterols and bile acids are properly dealt with in vol. 14, some of their tricyclic degradation products (for example, ætiobilianic acid) appear in the present volume. In other cases the names only are given, with cross-references to volume 14, and this method of treatment, although not strictly logical, is to be preferred. The present volume also includes a number of phenanthrene derivatives obtained by degradation of alkaloids such as morphine and thebaine, corytuberine, glaucine, boldine, laurepukine and artabotrine. The English style of the work is satisfactory, and only very rare lapses betray the Continental origin of the publication. The British reader, for example, will probably be mystified by expressions such as "fat coals" (p. 28) and "brutto formula" (p. 207). There are an excellent subject index and a comprehensive formula index.

In the opinion of the reviewer it is deplorable, in the present state of organic chemical documentation, that the duplication of effort involved in the production of both Beilstein's "Handbuch" and Elsevier's "Encyclopædia" should continue. It would be equally deplorable if the tremendous amount of labour already put into either project should be wasted. What is needed is an amalgamation of the two organisations, with the view of concentrating all the available resources on the rapid completion of an up-to-date comprehensive survey of the organic chemical literature. It is clearly desirable that use should be made of modern methods of punched cards and mechanical sorting systems, in conjunction with a cyphering system such as the elegant and ingenious system of Dyson. Only by the use of every possible device can the herculean task be accomplished. The provision of a complete survey of the literature of all organic compounds is an international service, and the project should be conducted under international sponsorship, provided always that this can be made fully effective, with adequate resources. Organic chemists throughout the world should speak with united voice on the urgent and imperative need for resolute action on these lines. J. W. COOK

PROBITS

Probit Analysis

A Statistical Treatment of the Sigmoid Response Curve. By D. J. Finney. Pp. xiii+256. (Cambridge: At the University Press, 1947.) 18*s*. net.

BOOKS on statistics are apt to be either shallow or obscure. A book which avoided both these dangers and yet covered the whole field would have to be a very long book; but it is possible to achieve both profundity and perspicuity by restricting the scope of the book to the discussion of one technique, and this device has been adopted in a new book by D. J. Finney.

Whatever we may think of its etymology, the word 'probit' (probability-unit) has become firmly embedded. It was introduced by C. I. Bliss to denote a function into which percentages are converted in order to facilitate computation. When the dose of a poison is plotted against the percentage mortality, an S-shaped curve is obtained; but when the logarithm of the dose is plotted against the probit of the mortality, the results can usually be fitted with a linear regression line. A report dealing with this technique was published by the Medical Research Council in 1933, but this report has long been unobtainable. In the meantime, the subject has become more complicated, and many biologists and others will welcome the appearance of a complete text-book dealing with the whole subject. The book contains a history of the method, a discussion of its mathematical basis, full details about the use of a calculating machine for working out an example, a large number of other examples with less detail, and all the necessary special tables.

There is also much discussion of the more complex applications of probits, and it is really surprising to see what an elaborate subject this has become. Allowance can be made, by Abbott's formula, for the mortality in control groups of animals receiving no poison, and methods are given for calculating the maximum likelihood solution in this case. When the mortality depends on two factors, such as dose and time of exposure, the results can be interpreted by calculating the probit plane. When two poisons act together, or when one poison acts in two ways, the results will not, in general, be fitted by a straight line, and the shapes of the curves to be expected in this case are discussed. Methods are given for analysing the variance of the sensitivity of the animals when tests are carried out on different days. The case when each animal receives a different dose is discussed. A section is devoted to the general formula proposed by Parker-Rhodes which includes, as special cases, both the normal distribution of individual lethal doses and the normal distribution of the logarithm of this quantity. The last chapter refers briefly to the treatment of the results of tests in which the response of each animal is measured quantitatively, as, for example, when a vitamin is estimated by its effect on the weight of rats.

The book will serve as a valuable guide to this branch of statistics. Everyone who is interested will be able to learn something from it. The novice will find full instructions for making complicated calculations, and even the experts will find things that they did not know before. There is, however, one criticism to be made. In previous writings on this subject the symbol λ has been used to denote the standard deviation of the logarithm of the independent variate, such as the dose. This notation was proposed because σ commonly denotes the standard deviation calculated directly, and it is convenient to use a different symbol when logarithms are used. This convention is not necessarily good, but has been widely adopted; it is therefore unfortunate that in this new book the same rather exotic symbol is used to denote the dose. Surely some other symbol might have been found for this purpose.

J. H. GADDUM

DATA FOR NUCLEAR PHYSICS

Nuclear Physics Tables

By J. Mattauch; and An Introduction to Nuclear Physics, by S. Fluegge. Translated from the German by Eugene P. Gross and S. Bargmann. (Published and distributed in the Public Interest with the consent of the Alien Property Custodian.) Pp. viii + 173 + 8 plates. (New York and London: Interscience Publishers, Inc., 1946.) 72*s*.

THIS work combines a comprehensive set of tables of nuclear physics data compiled by J. Mattauch with an introduction to nuclear physics by S. Fluegge. It was first published in Germany in 1941 and has now been republished in the United States by Interscience Publishers.

The first table gives a list of all the measured constants of stable nuclei. This includes relative abundance, spin, magnetic moment, quadrupole moment, and mass defect. The third table gives mass differences for all the important doublets used in the mass-spectrograph determinations of isotopic weights. The fourth table gives a list of all isotopes, stable and unstable, and their isotopic weights with probable errors of the determination. It gives the details of half-life, radiations emitted and method of formation for all radioactive isotopes. This table is specially valuable since it provides in separate columns for the thirteen common methods of formation of radioactive isotopes, (α, p), (α, n), (p, γ), (p, n), etc. It is possible, therefore, to see very quickly all the known reactions, say, of the (n, γ) type or, for example, to look up a specific positron emitter having a positron energy above a desired value. The sixth table gives a list of energy yields (Q values) of a large number of nuclear reactions of atomic number less than 33.

There is finally a chart of the well-known 'wall type' in which all known nuclei are represented by black, red or green squares depending on whether they are stable, unstable or isomeric, while arrows show all possible transitions.

The tables are complete with references, and contain all information available in 1941. Their principal deficiency to-day is in the list of fission products and their properties, most of this information having been released within the last year by the various atomic energy projects.

Information on nuclear absorption and scattering cross-sections is conspicuously lacking, and is a second deficiency. A good deal of this information was available in 1941, and much better and more complete information is now available.

The "Introduction to Nuclear Physics" comprises 109 pages. It includes subjects such as K-capture, isomerism and the meson theory of nuclear forces which have not been available in earlier text-books. Mass spectrographs and methods of calculation of mass defects are treated fully, as are experimental methods of determination of nuclear spin and nuclear moments. The chapter describing methods of observation in nuclear physics, such as ionization chambers, counters and amplifiers, is now out of date owing to the important developments in technique during the war years.

The book, therefore, fills a gap in existing literature in nuclear physics; but it is rather far from satisfying the need for a really comprehensive text-book embodying all the published knowledge now available.

J. D. COCKCROFT

BIOLOGY OF THE LOUSE

The Louse

An Account of the Lice which Infest Man, their Medical Importance and Control. By Prof. Patrick A. Buxton. Second edition. Pp. viii+164. (London: Edward Arnold and Co., 1947.) 10*s*. 6*d*. net.

THE louse (*Pediculus humanus*) is a highly specific parasite of man. Prof. Buxton's book deals with this creature more especially from the biological and medical points of view. It is an insect of great importance in human economy since it is well known to be concerned in the transmission of epidemic, or exanthematous, typhus from one person to another. The epidemic type of relapsing fever is also transmitted by it, as is the disease known as trench fever. The latter malady was a major factor in the health of the opposing armies in the First World War; but its actual or apparent disappearance since its close has yet to be explained.

The new edition of Prof. Buxton's book bears testimony to the great increase in knowledge of the louse since the appearance of the first edition in 1939. Ideas and knowledge of louse control have been well-nigh revolutionized in that interval, particularly owing to the fortunate discovery of the remarkable effects on the insect of the compound known as *D.D.T.* The wide use made of this substance in the great typhus outbreak in Naples in 1944 led to the epidemic being arrested in the course of about half a year. Tens of thousands of persons at one time were treated daily simply by blowing *D.D.T.* as a dust under the garments, without any undressing being involved. Even more effective is the impregnation of clothes with *D.D.T.*, since this compound retains its lice-killing properties after they have been worn for several weeks and repeatedly washed with hot soap and water. It appears that an impregnation of 1 per cent by weight of garments in store with *D.D.T.* enables them to retain their insecticidal properties to a large extent even after a year. As Prof. Buxton remarks, the efficiency of *D.D.T.* in louse control is so great that perhaps we have now seen the last great typhus epidemic.

The study of the collective biology of louse populations has virtually come into existence in the short interval since 1939, mostly through Prof. Buxton's own researches. Also, Wigglesworth's work on the sensory physiology of the insect is a further noteworthy advance in our understanding of its behaviour. These, and many other aspects of the louse in relation to man, are fully dealt with in this authoritative and indispensable little book. Being written with a breadth of viewpoint only to be acquired by a truly scientific outlook, we commend it not only to medical officers but also to entomologists the world over. Another feature is the very complete bibliography of louse lore that accompanies the text of this manual.

A. D. IMMS

The Detection and Control of Garden Pests

By G. Fox Wilson. (Agricultural and Horticultural Series.) Pp. 194+54 plates. (London: Crosby Lockwood and Son, Ltd., 1947.) 12*s.* 6*d.* net.

A GOOD sound book on pests of the garden has long been overdue, and Mr. Fox Wilson's effort certainly fills the gap admirably. Very often insect damage to cultivated plants is uncommonly difficult to identify. Unless it can be recognized in its early stages and measures of repression put into force, it is usually "too late to mend". The book is an expanded and revised version of the author's serial articles entitled "Symptoms of Pest Attack on Plants" published in the *Gardener's Chronicle* during 1932–36. The basis of the book is, therefore, laid on diagnosing pest injuries, and each chapter deals with the insects or other pests of a separate part of plants. Thus Chapter 3 deals with roots, and here the reader will find an account of the injuries inflicted by all the root-enemies that are likely to be encountered. Other chapters deal with stems and shoots, flowers, seeds, and so on. There is no doubt that this method of treating the subject facilitates quick identification better than any method of grouping the different pests under their natural orders or their specific plants.

The measures advocated for the control of the various pests are the best that present-day knowledge can offer—some are completely effective, others partially so. The photographic illustrations of damaged plants are a useful aid together with those of individual pests. While the nomenclature used for different pests is not always very modern, little confusion will result. In fact, it will prove an advantage to the general reader for the reason that it will facilitate reference to works of earlier date, since in these works the older names are current.

The author has done a real service in writing this book at a time when we need to produce and conserve so much in the vegetable kingdom. A. D. I.

The Adjustment and Testing of Telescope Objectives

By H. Dennis Taylor. Fourth edition. Pp. viii+95. (Newcastle-upon-Tyne: Sir Howard Grubb, Parsons and Co., 1946.) 17*s.* 6*d.*

THOUGH the first edition of this work was published more than fifty years ago, in 1891, it still has value as a standard work on the adjustment and testing of telescope objectives. The firm of Sir Howard Grubb, Parsons and Co., which has taken over the astronomical interests of Messrs. Cooke, Troughton and Simms, has performed a useful service in publishing a new edition. This edition follows the text of the third edition, published in 1921. The new edition would have had a greatly increased value, however, if the opportunity had been taken to revise the material thoroughly and to make additions to bring it up to date. New methods of testing objectives are available and might well have been included. The introduction to the volume refers to the refracting telescope as "the most convenient and generally reliable form of telescope"; but since this was written the reflecting telescope has become much more favoured. All large modern telescopes are necessarily reflectors, and reflectors are much used by amateurs because, for a given aperture, a reflector is less costly than a refractor and also because mirror making is within the ability of many amateurs. It would have been valuable to have included an account of methods of testing mirrors—spherical, paraboloidal and hyperboloidal. Other material could with advantage now be omitted as not strictly pertinent to the subject of the book. At some future date, a new edition is likely to be required, and it is suggested that the opportunity might then be taken to make a complete revision.

I fondamenti scientifici della astronomia

Per Prof. G. Armellini. Pp. xv+320. (Milano: Ulrico Hoepli, 1947.) 650 lire.

THE aim of the author in writing this book was to fill a gap in Italian scientific literature by presenting a logical mathematical account of the foundations of that part of astronomy which is concerned with the study of the movements of the celestial bodies, and with the calculation of their distances and of their dimensions. The book is intended primarily for the students attending courses in astronomy at Italian universities, and the knowledge of mathematics required does not go beyond simple applications of the differential calculus. In addition to the ground usually covered in elementary text-books on spherical astronomy, the author deals with the calculation of an orbit from three observations, with the determination of the solar motion, with the rotation of the galaxy and the determination of its dimensions and mass, with elementary stellar statistics and dynamics, with the distribution of the external galaxies and with the curvature of space. Most of the subjects dealt with are necessarily discussed only in an introductory manner. The student who masters this book will, however, have a sufficient grounding to enable him to proceed to the study of more advanced text-books. The author plans to follow this work with a further volume on the scientific foundations of astrophysics, which will be concerned with stellar photometry, astronomical spectroscopy, and the physics of the sun, planets, stars and nebulæ. H. S. J.

Native Peoples of the Pacific World

By Prof. Felix M. Keesing. (Pacific World Series.) Pp. xv+144+32 plates. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1946.) 15*s.* net.

FOR most people there is a strange glamour about the South Sea Islands and their inhabitants, due in part, no doubt, to the works of such visitors as R. L. Stevenson and Gauguin. But few people know anything accurately either about the islands themselves or about the various peoples who live there, their material culture, customs, etc.

This book, written mainly for American soldiers during the War, sets out to supply this need, and it has the great advantage of being written by a specialist; Prof. F. M. Keesing was born in Malaya, brought up in New Zealand, and has been professor of anthropology in the University of Hawaii. He is at present professor of anthropology in Stanford University, California. After a general chapter on the geography of the South Sea Islands, the Polynesians, Micronesians and Melanesians are in turn briefly described, such matters as languages, types of government, methods of livelihood, home conditions and social customs being mentioned. Finally, there is a chapter on religion. The whole is profusely illustrated and the work is very readable. Unfortunately, there is no bibliography; but a beginner interested in these far-away peoples will here find an excellent introduction to the subject. M. C. B.

THE DRAINING OF BINLEY LAKE AND ITS ECOLOGICAL CONSEQUENCES

By WING-COMMANDER T. R. CAVE-BROWNE-CAVE, C.B.E.*

A DESCRIPTION of the formation of drainage channels in the mud exposed by draining a large lake and the exceptionally rapid growth of vegetation on the lake bed may be of some general interest. The work was done for camouflage during the War.

A large expanse of water is the most outstanding landmark seen from the air at night. To an airman who knows how to approach it from the correct quarter in suitable conditions of light, it will shine out in sharp contrast with the general darkness of the landscape. A few miles to the east of Coventry is Binley Lake, some 90 acres in extent, and of a most distinctive horse-shoe shape. It would be an invaluable landmark to an enemy approaching a target so far from the coastline. It was therefore decided, after consultation with the Air Staff, to drain the Lake in order to suppress its outstanding appearance.

The Lake contained a great quantity of coarse fish, and the owners derived very considerable revenue from fishing. But their co-operation was prompt and most helpful. A stream flowed into one end of the Lake. Water passed out through sluices so placed that the Lake would drain without difficulty when they were fully opened. Arrangements were made with the Fishery Board of the area to net the fish and transfer them to streams and reservoirs in the neighbourhood. The experts who did the work estimated that they successfully decanted nearly a million fish, ranging from pike of more than 20 lb. to bream of about 20 gm. The netting process necessitated lowering the water-level very slowly. When most of the important fish were out, the last of the water was released. That left ninety acres of flat wet mud which would shine and reveal the distinctive shape just as well as the water would have done. Even if the bed did dry out during the summer, it would return to its wet brilliance after every heavy rain storm. It was considered that not until the mud was well drained and aerated after several seasons would there be any strong growth of vegetation. The mud was very soft and 4–6 ft. deep. Any work of artificial drainage would have been almost impossible. There was, however, such a complete absence of those drainage channels which appear in mud flats left by the tide in an estuary that it seemed worth while to arrange for another 'tide', which ebbed more rapidly.

The Lake was allowed to refill to a depth of some 12 inches. The sluices were then opened wide, so as to get the maximum possible rate of outflow. In less than two hours, a perfect system of drainage channels started to develop and gradually spread over the whole area in perfect pattern. It was therefore probable that the mud would gradually dry out and would not re-flood, because rain storms would tend to cut the channels deeper. Fig. 1 is from a photograph taken on November 13, 1942, from the outlet sluices, a few hours after drainage was complete.

The site was examined occasionally from the air until it was obvious that the mud had dried so well that there was no risk of shine. It was not until some eight months later—November to July—that a further survey was made. The report was rather surprising, so an examination on the ground was made. The lake bed was completely covered by dense vegetation. Fig. 2 is from a photograph taken on September 22, 1943, from the same point as Fig. 1, but ten months later and in a slightly different direction. The expanse of supposedly waterlogged and sterile mud was covered with a dense growth, including some willows more than 8 ft. high. Presumably the drainage and aeration had been rather better than expected. The crust had hardened sufficiently to allow men to walk across the Lake with circumspection; but there was a pronounced jelly-like movement which suggested the mud underneath.

There can be no doubt of the excellence of the camouflage. The cost of making the change was small. It may be significant that, although Coventry had been heavily raided on two occasions previous to the draining, two raiders which came to that area not long after the Lake was drained dropped their bombs in open country within ten or fifteen miles of the vitally important area.

After the need for camouflage had ceased, the problem of returning the Lake to its owners and determining the extent of compensation arose. Expert advice was taken upon the action which would most promptly enable the lake bed to return to a condition in which the Lake could satisfactorily be

FIG. 2. VEGETATION COVERING THE BED OF BINLEY LAKE TEN MONTHS AFTER DRAINING

re-stocked. It was considered that until the Lake was reasonably clear of rotting vegetation, the oxygen content of the water would be too low to justify re-stocking with fish. It was also doubtful whether 6–8 ft. of water would be sufficient to kill the vigorous growth which had arisen during the two years the Lake had been empty.

The owners were therefore advised that the vegetation should be cut close down in the spring, the autumn and the following spring before the Lake was re-flooded. Compensation was based upon this suggestion, and allowance was made for a reasonable period before the Lake and its fish could be expected to have recovered full fishing value. The owners decided, however, not to incur the expense of cutting, and they re-flooded the Lake in October 1944, almost exactly two years after it had been drained.

A visit to the Lake in August 1947 showed that during two seasons a few men had been employed in pulling out the bullrushes and similar growth which showed above the surface. In March 1946 there were large areas of open water with belts of reedmace at the shores. Some eight thousand roach, bream, pike, rudd and tench were then put in; a further seven thousand, with some golden carp, were added in September 1946. All seemed well until in July 1947 a strong growth of hornwort (*Ceratophyllum demersum*) developed in almost every part of the Lake. The growth extended to the surface in many places, where it entrained a quantity of ordinary pond weed and made fishing almost impossible. The fish, however, appeared to thrive. No dead fish have been seen, and those caught show good growth and are in good condition.

The problem now is to find what action can be taken without injury to the fish to avoid the growth of weed in subsequent years.

Dr. W. B. Turrill and Mr. V. S. Summerhayes, of Kew, visited the Lake in December 1943, and a brief summary of their findings is appended.

VEGETATION AFTER DRAINING

By V. S. SUMMERHAYES and DR. W. B. TURRILL

A visit to Binley Lake was made on December 2, 1943, under the guidance of Mr. F. P. Knight, of the Directorate of Camouflage. The Lake had been drained and its bed was occupied by a dense growth of vegetation fairly uniformly spread over the whole area. The dominant plant was the reedmace (*Typha latifolia*), except in a few small patches where other species (mainly *Phragmites communis* and *Carex* sp.) had obviously established themselves, previous to the draining, in shallow water against the shore. The reedmace plants were up to 6–8 ft. in height, and a very large number of them were in full fruit. Though they were distributed over the whole lake bed, the mature plants of reedmace were somewhat denser in some parts than in others. In places willows (*Salix capræa* and *S. viminalis*) had become established and were 8 ft. tall. Locally these willows were abundant. The reed grasses *Phragmites communis* and *Glyceria maxima* occurred in a few places, and many marsh and some dry-land species were listed as present in one to several individuals. It was fully established, from the morphology of the *Typha* and other plants, that this remarkable growth of vegetation had occurred within one year. The botanical evidence was in complete agreement with the dated records that the fruiting *Typha* plants had developed from seedlings in less than twelve months, a surprising rapidity of growth from establishment on bare mud.

The vegetation was only partially closed. In many places, leaves of separate plants touched or overlapped, but there was mostly bare mud between individual plants. On this mud were innumerable seedlings of *Typha*, low-growing marsh plants, some in flower or fruit, and mosses. The presence of mosses was not unexpected; but the species represented were mostly well-known dry land ones. Far and away the most abundant was a form of *Funaria hygrometrica*, which sometimes appeared in continuous patches a foot or more square, but more often in smaller clumps. Other species present in fair quantity, but scattered throughout much of the area of the lake bed, were: *Barbula unguiculata*, *B. tophacea*, *Bryum argenteum*, and *Bryum* sp. (barren). Small quantities of *Webera carnea* and *Dicranella heteromalla* were also noticed, and one patch of the liverwort *Marchantia polymorpha* was found near the inlet end of the Lake.

The reedmace which, at the time of the visit, had so largely occupied the mud, must have spread as seeds from near the top (inflow) end of the Lake, where there was an old-established community of this species forming what had evidently been a *Typha* swamp. No other *Typha* was found growing in or near the Lake, except the young plants and seedlings all less than a year old.

PHYSIOLOGY OF DISEASE RESISTANCE IN PLANTS

AT the Royal Society symposium held on December 11 on the "Physiology of Resistance to Disease in Plants", three papers, by Prof. W. Brown of the Imperial College of Science and Technology, Prof. F. T. Brooks of the University of Cambridge and Dr. F. C. Bawden of the Rothamsted Experimental Station, respectively, were read. Unfortunately, there was no time for a general discussion at the end of the papers.

Prof. W. Brown claimed that physiological analysis of the host-parasite relationship is most readily attempted in the case of the facultative parasite. The latter can be cultivated *in vitro* and its metabolism, therefore, studied up to the limits set by available experimental techniques. One can thus obtain some idea of the means by which fungi and bacteria attack plants—the so-called 'offensive mechanism' of the parasite—and conversely of the resistance which plants are able to oppose to such attack. The establishment of parasitism involves the carrying out of a series of operations which will be discussed in the following sequence: (1) pre-penetration phase, (2) the act of penetration, and (3) post-penetration phase.

In the pre-penetration phase the first requisite is that spore germination should take place. The more vigorous the germination the more likely is penetration to occur. Moist conditions, that is, presence of free water or of a sufficiently high relative humidity, are essential, and these must persist for a time sufficient to allow of germination and entrance into the host, otherwise death of the germ-tubes by desiccation would result. Meteorological conditions largely determine whether a particular plant disease can establish itself or whether alternatively it reaches epidemic proportions. Even under wet-weather conditions, some plants are protected from invasion by possessing an unwettable type of surface, so that one of the preliminary conditions for infection is not satisfied. This is an example of 'disease escape', the plant not being attacked even though it may be inherently susceptible.

Granted suitable environmental conditions, the germinative capacity of the spores of any fungus varies with their age and with the conditions of culture under which they were grown. A factor of importance at this stage is the passive exosmosis of solutes from the underlying host cells, and these affect the amount and vigour of spore germination according to their quantity and quality. The presence of other fungi or of bacteria in the inoculum has in general a depressing effect on germination and therefore on the establishment of parasitism. This is an example of microbiological antagonism which is more prominently shown with certain root-invading fungi.

The stimulus to penetration was at one time considered to be of chemotropic nature, but that view has been largely discarded. With fungi which penetrate directly through the cuticle, the stimulus is one of mechanical contact, the germ tubes becoming fixed to the surface of the host by formation of an appressorium (attachment organ), at which point they attempt to penetrate. The mechanism of penetration is also physical, the fungus putting an extremely fine outgrowth through the cuticle. The evidence on this point is partly cytological and partly that no cuticle-dissolving substance is known to be produced by fungi. The mechanical properties of cuticularized epidermis and the intrinsic penetrative capacities of fungi are the determining factors at this stage. A part of cuticular resistance depends upon the hydrostatic backing of the underlying epidermal cells. By these means one can explain the penetration of young or old leaves when the leaf is not penetrable in its mature, fully active condition.

Cuticular resistance is the only means of defence of some plants against specific parasites (wound parasites). Frequently the cuticular barrier is circumvented by invasion through stomata or other natural opening, or by way of parts (for example, the stigmas of flowers) where the cuticle is poorly developed. Once inside the plant, parasites of the facultative type disorganise the host tissue and live on the dead remains. The chief substance concerned in this process is pectinase enzyme. Resistance may take the form of retardation or inhibition of growth of the invader or interference with its offensive mechanism. Thus acidity of cell-sap, or presence of tannins, oils, glucosides, etc., may prevent growth of a potential parasite. A similar effect is obtained when the metabolism of the latter leads to the formation of substances ('staling substances') which by and by inhibit growth; hence the formation of lesions of limited size.

The reaction of the host to the presence of the parasite may be to lay down mechanical barriers (gum, cork) which seal off the lesion. Chemical responses, for example, the localized formation of phenolic compounds, may occur; but it is not clear how far these are effective. It is very doubtful if there is in plant pathology (apart from some viruses) an antigen-antibody type of reaction comparable to what is known in animal diseases.

A more general type of resistance is seen where, in the absence of any obvious anti-fungal property of the plant sap, the plant in its normal condition shows resistance to a fungus which appears to have the necessary offensive mechanism. Slight modifications of the host, as produced by raising its water-content or by previous incubation at a warm temperature, may swing resistance over to susceptibility. Other components of this problem are the differential effects of nutrient upon the capacity of fungi to produce pectinase, and differences in detailed properties of pectinase as derived from various fungi. The continuance or otherwise of attack appears to rest upon the functioning of an intricate enzymic process, the details of which have not been worked out as yet.

Finally, there is a kind of resistance which depends upon insensitiveness of the plant tissue to the enzymic secretion of the fungus. As the primary enzymic effect is hydrolysis of the cell walls, the factor which confers immunity in this case is the chemical composition of the cell wall.

Prof. F. T. Brooks pointed out that the fundamental difficulty met with in studying the physiology of obligate parasites is that the fungus cannot be grown on culture media and thus has to be studied in relation to the host itself. The relationship of host and parasite is bound up with subtle protoplasmic properties of the two organisms, though even here there is some evidence that structural properties of the host confer a measure of resistance; for example, the presence of a greater amount of sclerenchyma in certain wheats, the thickness of the mature cuticle in the barberry leaf which resists penetration by the germinating sporidia, etc. Resistance of cereals to rust attack has long been known to rest upon the 'hypersensitive' effect, invasion by the fungus leading to localized necrosis of the host cells, so that further advance of the parasite is stopped. With the fully susceptible host the rust establishes a kind of common life with the invaded tissue and there is no evidence of mutual antagonism. Intergrades between the two types of reaction occur.

One can do little more than speculate as to the physiological nature of these reactions. It has been suggested that hypersensitiveness arises by the excretion from the fungus of a toxin and that the fungus eventually dies from starvation or more probably through the agency of lethal substances excreted by the host. No satisfactory explanation in biochemical terms is as yet available of the difference between susceptible and resistant host varieties.

The hypersensitive reaction is affected by changes in the environment; for example, by nutritional alterations of the host as brought about by varied illumination or by differential manuring, and even by the presence of another parasite in the tissue. Thus under certain conditions a susceptible host becomes resistant and *vice versa*. Frequently susceptibility in seedling cereal plants gives way to resistance as the plants grow older ('mature plant resistance'). This effect is of great practical importance, but its physiological meaning is unknown.

Resistance to attack by mildews first becomes evident at the stage where a sub-cuticular papilla is formed. Whereas in a susceptible host a haustorium emerges from the papilla to invade the underlying epidermal cell, such emergence does not occur where there is resistance. The host cell is undamaged, though a hypersensitive effect has also been described. A similar range of behaviours is seen in connexion with the invasion of potato varieties by the wart disease fungus, though here the striking response is the large development of gall tissue when the variety is susceptible.

With certain facultative parasites there are defensive mechanisms in resistant hosts which, while not preventing initial invasion, preclude the fungus from spreading extensively in the tissues. Such is the gum barrier produced from wood carbohydrates when a resistant variety of plum is invaded by the silver-leaf fungus. A susceptible variety produces no such protective barrier, though under conditions of enhanced metabolism it may do so to some extent. Resistance to the root-invading fungus, *Armillaria mellea*, also appears to be due in part to the gumming reaction, though here cork barriers are developed in addition. The functioning of cork barriers is well seen in varieties of apple trees resistant to canker; in this case the effectiveness of the barrier is largely dependent upon the state of metabolism of the host, so that under some conditions a normally resistant variety becomes susceptible. The well-known 'shot-hole' appearance in the leaves of many plants is often due to the limitation of the lesion by a cork barrier.

Resistance to wilt-producing fungi appears to arise in a number of ways. With flax-wilt, resistance is seated in the cortex of the roots, so that the fungus is shut off from reaching the vascular bundles. In hop varieties resistant to wilt, the fungus enters the vessels, where it grows much as in a susceptible variety, but no harm ensues. It has always been considered that the wilting effect is due to the formation by the fungus of a toxin, and recently the toxin of tomato wilt has been identified as a polypeptide of known composition. Presumably the resistance of certain hop varieties to wilt is due to the non-elaboration of a toxin, or to insensitiveness of these varieties to the toxin produced. In some cases resistance of plants to wilt appears to be a property of the root only, in others of the whole plant.

Among the few examples in which resistance to fungal invasion is associated with particular substances of known composition, the best known is that of coloured types of onion against certain parasites. In contrast to white varieties of onion, which are susceptible, coloured ones owe their resistance to the presence in their outer scales of catechol and protocatechuic acid.

Resistance is rarely absolute under all conditions. The precise result obtained depends to some extent on the amount of inoculum applied and on environmental factors as affecting both host and parasite. The latter has already been referred to in connexion with resistance of cereals to rusts. A notable example of the effect of temperature on disease response is seen with the scab disease (*Fusarium*) of wheat and maize. Wheat seedlings are susceptible at the higher, maize seedlings at the lower temperature ranges, and in both cases it has been shown that susceptibility is correlated with a pectic type of cell-wall structure, the temperature under which the plants were grown being the determining factor for this.

Dr. F. C. Bawden dealt mainly with viruses. These are unique pathogens, for they are both wound parasites and obligate parasites. All uninjured plants are immune from all viruses, and most viruses have a narrow host range. Thus immunity is the common state, susceptibility is exceptional. Nothing is known of the conditions conferring natural immunity. The growth requirements of viruses are unknown, and though plant extracts often contain virus inhibitors it is uncertain whether these substances function as such *in vivo*. One is, therefore, limited to considering variations in degree and type of resistance shown by susceptible plants.

Viruses rely for transmission on vectors, chiefly leaf-sucking insects, and usually produce systemic infections. Possibly because of their systemic nature, virus diseases provide the only authentic examples of acquired resistance in plant pathology. There are two types, both simulating conditions well known with animal diseases. In the first type, infection leads to severe initial symptoms, from which the plants recover, and then resist effects of further inoculation. The recovery is not because of antibody formation, and the virus is present all the time in the resistant tissues. The second type of acquired resistance simulates the process of vaccination in animals: protection against a severe strain of a virus is given by previous infection with a mild strain. Again there is no antibody formed. Protection is based on mutual antagonism between the two viruses. It is suggested that there are only a limited number of sites of virus multiplication in a cell, and if these are occupied by one strain another cannot become established. The resistance is acquired only against related strains, and unrelated viruses may act synergistically, giving together severe symptoms when each alone gives only mild.

Virulence is not an intrinsic property of a virus strain but a reflexion of a host-parasite interaction, and is not correlated with the concentration of virus reached within the plant. Strains of potato virus *X*, for example, may cause severe diseases in some potato varieties and not in others. Hypersensitiveness, similar to that of cereals to rust fungi, affords a common form of resistance. Sometimes, however, there is a systemic hypersensitiveness in which the whole plant is invaded and killed. This is the extreme of susceptibility, but confers resistance by eliminating the virus from the stock as a whole. Varieties of potato which react to virus X in this way are rarely found infected in the field, whereas other varieties are almost universally so.

Short of hypersensitiveness, intermediate degrees of tolerance occur, down to the condition of 'carrier' varieties which show no symptoms though they may contain a high concentration of virus. The degree of tolerance is somewhat modified by environmental conditions.

With equal chance of infection, a greater incidence of disease occurs in some varieties than in others. This has been demonstrated both in field and controlled experiments. The inference is that different amounts of virus are needed to cause infection in different hosts. Though the evidence from dilution curves is that infection is caused by single virus particles, it seems that different numbers must be introduced into different cells to ensure that one becomes established.

With some viruses infection occurs only when the particles are introduced directly into the phloem; more often introduction into ordinary parenchyma cells is sufficient. The method of inoculation can affect susceptibility, infection taking place more readily when the inoculum includes a suitable abrasive. The severity of the symptoms shown may also be increased by this means.

An effect comparable to the 'mature plant' resistance of cereals to rust fungi is often seen, ease of infection and the severity of symptoms diminishing as the plant grows older. The cultural conditions of the host also influence resistance; thus some viruses are more readily transmitted in winter than in summer. The controlling factor appears to be light, and susceptibility to some viruses is enhanced by keeping the plants in darkness for 24 hours before inoculation. It is suggested that the presence of photosynthetic products interferes with the establishment of virus particles at sites of multiplication. The conditions of mineral nutrition are also important, phosphorus being most effective in increasing susceptibility, though quantitative comparisons are rendered difficult by unequal growth of the plant under different systems of manuring. Increased size of the plant itself tends to favour infection, and conversely small size gives plants a disease-escape mechanism which may simulate resistance in the field. Susceptible plants may also escape infection because they are unattractive to vectors or grow in situations which reduce the chance of visits by the appropriate insects.

CHEMISTRY OF VISUAL PROCESSES

By S. BALL, F. D. COLLINS, PROF. R. A. MORTON
AND
DR. A. L. STUBBS
Biochemistry Department, University of Liverpool

SINCE rhodopsin (visual purple) was first described in 1876 by F. Boll[1], much evidence concerning its chemical nature and physiological properties has accumulated. Relatively few attempts have been made, however, to devise theories embracing all the facts; the contributions of G. Wald[2], R. J. Lythgoe and his colleagues[3] and R. Granit and his co-workers[4] being outstanding. The objects of the present article are to describe experiments which seem to reconcile divergent findings, as between Wald and Lythgoe, and to provide a basis for discussing in chemical terms Granit's discoveries, concerning the electrophysiology of retinal elements.

It is necessary first to elucidate the decomposition of rhodopsin extracts. Wald[2] stated that retinene$_1$, later shown by Morton and Goodwin[5] to be vitamin A aldehyde, was the final product of bleaching. He was able to extract retinene from retinas freshly bleached by light, or from bleached solutions of rhodopsin, by using as solvent a mixture of acetone, ethanol and light petroleum. The retinene was identified by its ultra-violet absorption maximum 380–385 mμ in chloroform and its colour test maximum (664 mμ) with the antimony trichloride reagent. When a solution of rhodopsin in the aqueous digitonin used to detach the pigment from the retina was acidified before bleaching, the irradiated solution exhibited an absorption maximum at 443 mμ which afterwards disappeared, the final solution having the same general absorption on the long-wave side of 400 mμ as neutral or alkaline solutions. At that time Wald was not able to follow the absorption curves on the short-wave side. It seems clear, however, that he regarded retinene$_1$ as the sole and final product of bleaching rhodopsin *in vitro.*

Lythgoe and his co-workers were also restricted to wave-lengths exceeding about 395 mμ in recording absorption spectra. They observed that in acidified aqueous digitonin rhodopsin gave on irradiation 'indicator yellow' with $\lambda_{\max.}$ 444 mμ. In neutral or alkaline solution no maxima (at wave-lengths greater than 395 mμ) were observed. Lythgoe concluded that indicator yellow was the final product of bleaching rhodopsin; he suggested that it was a conjugated protein with $\lambda_{\max.}$ 444 mμ shown only in acid.

A. C. Krause[6] obtained a fraction from bovine retinas which exhibited $\lambda_{\max.}$ 444 mμ in acidified ethanol and 360 mμ when the solution was made alkaline. Krause obtained his materials from freshly bleached retinas rather than from rhodopsin solutions, and his findings are not strictly comparable.

The work carried out in our laboratory confirms and extends the observations made by both Wald and Lythgoe. Thus in neutral solutions rhodopsin bleaches to a substance exhibiting $\lambda_{\max.}$ 380 mμ and on which extraction by means of an ethanol – light petroleum mixture yields retinene$_1$ ($\lambda_{\max.}$ 385 mμ in chloroform, 664 mμ with the Carr–Price reagent). In acid solution, bleached rhodopsin shows $\lambda_{\max.}$ 440 mμ, and in alkaline solution $\lambda_{\max.}$ *c.* 360 mμ. In neither case is any absorbing material extracted by means of ethanol – petroleum mixture provided the pH is sufficiently different from 7. The substance giving rise in acid to the 440 mμ maximum is unstable even in the dark, and the final product is devoid of selective absorption. No retinene$_1$ can be extracted at that stage even after neutralization.

Further experiments have been carried out using pure retinene$_1$ obtained[7] by the oxidation of vitamin A. When dissolved in 1 per cent aqueous digitonin, pure retinene shows $\lambda_{\max.}$ 380 mμ, and the spectrum is unaffected by changing the pH of the medium. If, however, retinene$_1$ dissolved in aqueous alcohol or 1 per cent digitonin is mixed with one of the following: (*a*) an aqueous extract of bleached retinas, (*b*) a dialysed aqueous extract of choroid, (*c*) a solution containing a suitable protein, or (*d*) a solution containing a suitable amino-acid, absorption maxima at 440–460 mμ appear on acidification, or at 360–380 mμ in alkaline solution. The following proteins gave a positive result: egg albumin, trypsin, edestin, peptone. Gelatin, casein, zein and pepsin gave negative results. Of all the amino-acids tried, only β-alanine gave $\lambda_{\text{max.}}$ 440 mμ in acid solution. Arginine, aniline, *o*-toluidine, *o*-phenetidine hydrochloride, *p*-toluidine, diphenylamine and *p*-aminobenzoic acid all gave maxima at 500–525 mμ in acid solution. The reaction with *p*-aminobenzoic acid is interesting because the product responsible for the 535 mμ maximum is decomposed by light, and the consequent decrease in absorption at 535 mμ is accompanied by a rise at 390 mμ. Some interaction occurred between retinene$_1$ and the following, but was not accompanied on acidification by such marked changes in absorption: *d-iso*leucine, glycine, tryptophane, tyrosine, glutamic acid. Little or no effect was obtained with α-alanine, benzoic acid, dimethylamine, benzylamine, serine, benzoxazolone, pyridoxine, riboflavin, leucoriboflavin, phenol.

The conclusion to be drawn concerning 'indicator yellow' is that free or loosely bound retinene$_1$ (the final product of bleaching rhodopsin) may combine with any suitable protein or amino-acid which may be available. In that case 'indicator yellow' would be a fortuitous artefact having no direct relevance to visual chemistry, and Wald's cycle[2] connecting vitamin A retinene and rhodopsin need not be complicated by trying to fit in 'indicator yellow'.

Granit and his colleagues have greatly advanced the study of visual processes by the use of the microelectrode for picking up electrical impulses from optic nerve fibres subserving illuminated rods and/or cones. By using monochromatic light and measuring threshold intensities needed to obtain responses from rods or cones, action spectra can be arrived at.

At this point it is necessary to emphasize the distinction between an action spectrum and an absorption spectrum (cf. Dartnell and Goodeve[8], Hecht[9], Wald[2]). Granit[4] makes clear the distinction between equal energy and equal quantum action spectra. If I_0 is the incident intensity and I the emergent intensity of light of wave-length λ passing through unit area of 'retina' containing n absorbing molecules, $\log_{10} I_0/I = kn$, k varying with λ. If I_a is the intensity of absorbed light $I_a/I_0 = 1 - 10^{-kn} = a$, that is, fraction of light absorbed, and

$$100\, a\, \lambda/a_{\text{max.}} = 100(1 - 10^{-kn})/(1 - 10^{-k'n}) = \alpha.$$

Putting D for $k'n$ ('optical density' at $\lambda_{\text{max.}}$) and E for $100\, kn/k'n$, $kn = ED/100$ and

$$\alpha = 100\ \frac{(1 - 10^{-ED/100})}{1 - 10^{-D}}, \text{ or}$$

$$E = \frac{100}{D} \log \left(\frac{1}{1 - \frac{\alpha}{100}(1 - 10^{-D})} \right).$$

Plotting α against λ gives the action spectrum, and E against λ the absorption spectrum, α being the light absorption of wave-length λ expressed as a percentage of the absorption at $\lambda_{\text{max.}}$ and E being the extinction expressed as a percentage of $E_{\text{max.}}$ (D). When D is small, $E \simeq \alpha$; but action spectra and absorption spectra are not identical at higher values of D, thus:

VALUES OF E FOR DIFFERENT VALUES OF α AND D

a	D					
	0·01	0·05	0·1	0·2	0·3	0·5
20	19·8	19·2	18·2	16·7	15·2	12·8
50	49·7	48·6	47·1	44·2	41·5	36·3
80	79·8	79·0	78·1	76·0	73·7	68·8

Although the differences between α and E are very unlikely to vitiate any of Granit's findings, they may well become significant when comparisons between absorption spectra *in vitro* and his action spectra are used to try to trace the origin of the latter.

Granit's data imply the existence of a scotopic dominator (substance), the action spectrum manifested agreeing closely with the absorption spectrum of rhodopsin. A photopic dominator (substance) and several modulators must also be postulated. The dominators function in the perception of brightness and the modulators in colour discrimination. Evidence suggesting a chemical relatedness of the substances responsible for both dominator and modulator spectra emerges from the comparison of the data on eyes in which vitamin A (rhodopsin, retinene$_1$) occurs, and eyes in which vitamin A$_2$ (porphyropsin, retinene$_2$) is present (ref. 4, p. 290). In the two systems, corresponding absorption spectra and action spectra show parallel displacements. Bliss[10] recently recorded the extraction of retinene$_1$ from a solution of the photopic pigment iodopsin. It thus seems probable that vitamin A and its aldehyde occupy a key position in photopic and scotopic vision alike.

The action spectra of Granit's dominators correspond closely with the absorption spectra of rhodopsin and 'iodopsin'[11,12], $\lambda_{\text{max.}}$ 500 mμ and 560 mμ respectively. His modulators would correspond with much narrower absorption bands which have not hitherto been accounted for chemically. It seems that at least three chemical species must be postulated with narrow absorption bands in the visible region; they must be derived from a precursor (or precursors) available in the retina and they must have very special properties. The readiness with which vitamin A and retinene give rise to deeply blue-coloured solutions with antimony trichloride in chloroform, and the sharpness of the bands shown, coupled with the transient nature of the blue materials, suggest that with suitable environmental conditions retinene might give rise to ionized or halochromic molecules[13] resembling Granit's modulators.

It has been found that when vitamin A or retinene$_1$ is dissolved in concentrated sulphuric acid or syrupy phosphoric acid at temperatures near 0° C., coloured solutions are produced which exhibit well-defined selective absorption with maxima corresponding rather closely with Granit's maxima.

The absorption bands of the solutions derived from vitamin A and retinene$_1$ are narrower than those implied by Granit's action spectra. The solutions are sensitive both to light and heat, and in the 'fading' processes the maxima fall at different rates, suggesting the presence, not of one product with several bands, but of several products with one maximum to each. Although light hastens the fading, the solutions are not nearly so sensitive to light as are rhodopsin solutions.

WAVE-LENGTHS OF MAXIMUM ABSORPTION $\lambda_{max.}$ IN mμ

Rhodopsin		500					
Iodopsin				560			
Dominators		500		560			
Modulators	450–465	500	520–530		580–610		
Vitamin A in conc. H_2SO_4	465		530		590		620*
Vitamin A in conc. H_3PO_4	440–480		520			600	
Retinene$_1$ in conc. H_2SO_4	440–460		520	560			664*
Retinene$_1$ in conc. H_3PO_4	470	500		550	590		

* Shown better with the antimony trichloride reagent.

The conditions under which modulator analogues have been produced are obviously unphysiological. In the complete absence, however, of evidence for modulator precursors other than vitamin A and retinene$_1$ in rhodopsin eyes, the potentialities of these substances need to be explored. If it be granted that a *prima facie* case has been made out, the next and more difficult task will be to establish the physiological methods for stabilizing the modulator analogues.

It may be suggested tentatively that the greater width of Granit's modulator curves compared with the absorption bands of the analogues is consistent with a greater optical density of the modulators in cones than of rhodopsin in dark-adapted rods. Since the optical density varies as the product of molecular extinction coefficient and concentration, either or both could be important. The large difference between the thresholds of scotopic and photopic vision is well established; the quantum efficiency of the photo-decomposition of rhodopsin is nearly unity, and the molecular extinction coefficients of the modulator analogues are very high, but the substances fade less quickly than rhodopsin. The quantum efficiency of photochemical decomposition of modulators should thus be very low.

The photopic receptor substances, presumably conjugated proteins, may then be present at cone surfaces at relatively high optical density; they must be relatively thermostable as otherwise there would be a spontaneous sensation of light[14]; and finally, once detached from the protein moiety, halochromic or ionized prosthetic grouping derived from vitamin A or retinene would yield materials known to be present in retinas.

The special difficulties which are met in the study of photopic receptors make it important to pursue the study of the porphyropsin–retinene$_2$–vitamin A_2 system, because comparison of the rhodopsin–porphyropsin systems at all stages may be fruitful. The visual systems of invertebrates having eyes lacking either vitamin A_1 or A_2 present a further problem.

OBITUARY

Dr. A. L. Du Toit, F.R.S.

THE death of Alexander Logie Du Toit on February 25 has removed a particularly interesting figure from the stage of international geology. Born in South Africa on March 14, 1878, he received his early education at Bishop's College, Cape Town, whence he proceeded in turn to the Royal Technical College, Glasgow, and the Royal School of Mines, South Kensington. His connexion with Scotland is recalled by an important paper on Old Red Sandstone and Highland Border rocks, communicated to the Edinburgh Geological Society in 1902. Most of his researches, however, concern his home country, South Africa. At one time or another he held official positions on the Geological Survey and Irrigation Department of the Union; and later, in private practice, he acted for De Beers Consolidated Mines. In 1925 he led a government expedition to the Kalahari. His text-book, "The Geology of South Africa", published in Edinburgh in 1926, is indispensable to students of the subject, and includes welcome chapters on soil and economics.

In geology, as in astronomy, workers in the southern hemisphere have much that is special to tell their comrades of the north, because they look in a different direction. The southern continents, including India, are so closely comparable in their late Palæozoic and early Mesozoic histories that Suess long ago separated them from the rest of the world under the name Gondwanaland. In 1910, F. B. Taylor, and in 1912, A. Wegener, advocated continental drift on a scale that would account, without intervening subsidence, for the present apparently scattered distribution of the components of Gondwanaland. Du Toit had visited Australia by the time he learnt of the new hypothesis; and now, not content with further comparisons based on reading alone, he persuaded the Carnegie Institution of Washington to send him across to South America. Here, in Brazil, Uruguay and the Argentine, during the latter half of 1923, and with generous support from the local governments and geologists, he was able to accomplish a remarkable amount of field exploration, and to master the very difficult relevant literature. The results are set out in a Carnegie Institution publication entitled "A Geological Comparison of South America with South Africa" (1927). The treatment shows little mercy to readers, who have to stagger on under the impact of strange geographical and stratigraphical names; but the impression is conveyed that a path has been blazed through a hitherto impenetrable jungle. The author himself entertains no doubt as to the drift separation of South America and South Africa. He maintains the same outlook in "Our Wandering Continents" (1937), where a gallant attempt is made to rewrite the whole of world geology.

To turn to quite another aspect of the man, it is worth recording that among his friends Du Toit laid claim to the faculty of dowsing.

The Geological Society of London honoured Du Toit with the Wollaston Fund in 1919, and the Murchison Medal in 1933. These awards were fittingly bestowed during the presidencies of G. W. Lamplugh and Thomas Holland, who successively had learnt much of South African geology during visits of the British Association in 1905 and 1929. Du Toit was elected a fellow of the Royal Society in 1943.

E. B. BAILEY

NEWS and VIEWS

Czechoslovakia

WITHIN a few weeks of receiving the honorary doctorate of Brno University which bears his father's name, Dr. Jan Masaryk passed away at the age of sixty-one, on March 10, in tragic circumstances. Born and educated in Prague, he would not claim to have been a man of science, though he fully appreciated the importance of science in world affairs. He had occasionally taken part in scientific and cultural discussions and conferences while in Great Britain and elsewhere. Many philosophers and men prominent in various sciences were among his numerous friends, and he was always ready to help students and others whenever an opportunity occurred, whether it was in connexion with the exchange of scholarships or of scientific literature. Like his father, the former philosopher-president of Czechoslovakia, Jan Masaryk was a great European, and his death is a loss to the whole world as well as a very serious blow to Czechoslovakia at a critical time in her tragic history.

Prague is shortly to celebrate the sexcentenary of the founding of its famous university, and though Masaryk had no direct connexion with that institution his death cannot fail to cast a cloud over the ceremonies planned for this historic occasion. Unfortunately, too, recent events in Czechoslovakia have given rise to anxiety in Britain and elsewhere concerning the position and fate of several colleagues well known for their researches and other contributions to the advancement of knowledge. It is understood that some, including the rector of the Charles University, Dr. Karel Engliš, have been dismissed. Science and learning suffered heavily enough during the Nazi occupation through the closure of the universities and the execution of many members of their staffs, and to-day Czechoslovakia cannot afford to lose a single talented teacher or scientific worker. Masaryk certainly realized this. His attitude towards his fellows was one of encouragement and tolerance. It found expression, for example, when he was filling up an American immigration form and came to the question, "What Race?" His answer was, "I belong to the human race".

Prof. Bohumil Němec

PROF. BOHUMIL NĚMEC, the well-known botanist, celebrated his seventy-fifth anniversary in Prague on March 12, and we are glad to report that he was then in good health. He is at present engaged upon a comprehensive text-book of general botany in Slovak for use by students at Bratislava University and for upper forms in the Slovak high schools, and a history of botany which will have a wider appeal. Němec's first researches, on diplopods, appeared in the *Transactions of the Royal Bohemian Scientific Society* in 1895, and since then he has published many researches in plant physiology in Czech, English and other journals. Only recently he exhibited to scientific audiences in England and France specimens of gold that had been extracted from ashes of plants obtained from Slovakia. He has been interested in the occurrence in plants of unusual elements for many years. Němec is not only a great experimentalist and investigator but also an able lecturer, and many of his students have contributed to the advancement of pure and applied botany. Practically all Czechoslovakia's scientific forestry and agricultural experts studied under him at the Botanical Institute of the Charles University of Prague, which he directed for so many years. Since 1945 he has been occupied at the University of Bratislava in lecturing to Slovak students, and has advised on, and supervised, the establishment of botanical and physiological institutes in that University, which dates only from 1919.

Botany at Bedford College, London: Prof. L. J. Audus

DR. L. J. AUDUS, who has just been appointed to the Hildred Carlile chair of botany at Bedford College, London, is a distinguished member of the younger school of plant physiologists. He received his physiological training at Cambridge under the late Dr. F. F. Blackman, whose admirable tuition matured so many brilliant pupils. From Cambridge he went to University College, Cardiff, where he was lecturer in botany until he joined the Royal Air Force in 1941. He was stationed at Singapore, and when that city fell he escaped to Java, but was there captured by the Japanese. For three and a half years he was a prisoner in Java and Amboina, undergoing many hardships. During this period he collaborated with Dutch men of science who were fellow prisoners to organise an extremely resourceful manufacture of yeast-food, on a scale sufficient to keep vitamin starvation at bay and thus prevent what would otherwise have been a terrible mortality from beri-beri. Dr. Audus is no mean artist and the sketches he was able to bring home illustrate life in Japanese prison camps with dramatic clarity. On his return to Britain he was appointed to the Soil Metabolism Unit of the Agricultural Research Council, then situated at University College, Cardiff, under Dr. J. H. Quastel, and he was engaged in research on the action of growth-promoting substances in the soil. The Unit was closed at the end of 1947 with the departure of Dr. Quastel to Canada, and Dr. Audus had just been appointed as Monsanto lecturer in plant physiology at Cardiff when the opportunity of the appointment at Bedford College called him away. He goes accompanied by the regrets and best wishes of all his colleagues at Cardiff.

Max Planck Society for the Advancement of Scientific Research

THE Max Planck Society for the Advancement of Scientific Research was formed on February 26, with the approval of the Military Governments of the British and U.S. Zones of Germany. It will replace the Kaiser Wilhelm Society for the Advancement of Science which was dissolved in July 1946. The fact that the latter society had during the War come under the influences of the Nazi regime was one of the reasons for the order being given for its dissolution. The new Society, which will operate under the provisions of the Allied Control Council's law No. 25, relating to the control of scientific research, will have as its main object the encouragement of fundamental and independent research on peaceful lines. It will make it possible once more for the British and American Zones of Germany to be fully represented in the international field of scientific research. Otto Hahn, known for his fundamental research in nuclear fission, has been elected president, and Dr. Ernst Telschow, of Göttingen, who, since the end of the War, has played a leading part in maintaining scientific work in the U.S.–British

Zones, has been appointed general director. The following have been elected members of council: Prof. Edrich Retener, director of the Institute of Physics, Technical High School, Stuttgart; Prof. Adolf Windaus, formerly director of the Chemistry Institute, University of Göttingen; Dr. Wilhelm Boetzkef, Banking Boetzkef, banking director, of Düsseldorf; Prof. Georg Schrieber, professor of theology, University of Münster; Dr. Theo Goldschmidt, director of the chemical manufacturing firm in Essen bearing his name; Adolf Grimme, Minister for Education, Land Niedersachsen; Prof. Richard Kuhn, director of the Kaiser Wilhelm Institute for Medical Research, Heidelberg; Dr. Alfred Petersen, president of the Frankfurt Chamber of Commerce and Industry; Senator Landahl of Hamburg; and Prof. Heinrich Weiland, formerly director of the Institute of Chemistry, University of Munich. Prof. Hahn, Dr. Telschow and Prof. Max von Laue are *ex officio* members of council. In addition to the president and the general director, the following will constitute the administrative council: Prof. Retener (vice-president); Prof. von Laue (general secretary); Prof. Kuhn (deputy general secretary); Dr. Boetzkef (treasurer); and Dr. Petersen (deputy treasurer).

Serological Museum of Rutgers University

THERE has been established at Rutgers University, in New Jersey, a museum for the collection, preservation and study of the proteins of the blood and other tissues of the bodies of organisms, in the belief that such proteins are as characteristic as other constituents and are as worthy of preservation and comparison as skins and skeletons. The establishment of the Serological Museum is a logical consequence of the studies in systematic serology which have been conducted at Rutgers University since 1925, by Dr. Alan Boyden and his students and colleagues. Dr. Boyden has himself collected many representative samples of the blood sera of animals from laboratories in the United States and Great Britain, and others have been contributed by institutions and individuals; in recent years lyophilized (frozen and dried) samples of animal sera or of the purified fractions of such sera have been contributed by industrial laboratories. The principal objectives of the Serological Museum will be to preserve representative sera or other proteins of organisms and to study the means of improving methods of preservation; to build up a collection of sera and other proteins of as many kinds of organisms as possible; to share the samples collected with competent workers; and to study the methods used in systematic serology. Although the sera of hundreds of species of animals have already been collected, no group of animals is as yet adequately represented in the collection. The sera of many kinds of animals—vertebrate and invertebrate—are still needed. The growth of this Museum and its capacity for service will depend largely on co-operative efforts by many individuals and institutions. Those interested in the subject are invited to correspond with Dr. Alan Boyden, Rutgers University, New Brunswick, New Jersey, U.S.A.

Climatic and Ecological Changes in Northern Waters

AT the meeting of the North-Western Area Committee of the Conseil Permanent International pour l'Exploration de la Mer on October 22, 1947, the possible influence of the present climatic changes on the lives of marine animals (density, distribution, reproduction, migration, etc.) was discussed. Having regard to the probable importance of these changes in fisheries investigations, it was decided that every opportunity should be taken, by fishery research vessels and other suitable ships, to obtain without delay all possible data bearing upon this problem, especially in waters north of the Faroes, north and east of Iceland and in the Denmark and Davis Straits. It was also decided that relevant information from sources other than those of fisheries research would be of great value and should also be obtained. The information required comprises hydrographical, meteorological, glaciological and associated changes in northern regions, and the influence of those changes on the habits and distribution of animals and plants, both terrestrial and marine. Records should include locality (latitude and longitude), depth (if marine records), date, name and profession of observer, and references to relevant publications. Especially important are new records of animals and plants from localities recently included within their range of distribution, or the absence of species from previously populated areas. All data should be given exhaustively but concisely, and arranged so far as possible under the following headings: (1) meteorology; (2) hydrography; (3) glaciology; (4) animals: (*a*) Mammalia, (*b*) Aves, (*c*) Testudinata (especially observations on the west coasts of the British Isles), (*d*) Pisces, (*e*) Invertebrata; (5) plants; (6) other items. Contributions to this inquiry are earnestly requested from everyone in possession of useful information, and should be addressed to Dr. Å. Vedel Tåning, Charlottenlund Slot, Charlottenlund, Denmark, preferably during December of each year.

Science and Religion

FOR two hundred years, popular writers have attacked traditional religious beliefs in the name of science and pretty well undermined the faith of the plain man. Now, however, the sceptical attitude is turned against science itself, at a moment when, thanks to recent developments of physical theory, science appears vulnerable intellectually and, thanks to recent developments of military and political technique, still more vulnerable morally. Modern men, finding themselves with nothing to put their faith in, fill the spiritual vacuum with bogus religion based on bogus science, like Nazism and Communism. Even the more modest alternative, the assurance that all problems are technological and that the salvation of mankind depends on bigger and better gadgets, is not entirely satisfactory. The new quarterly magazine, *Science and Religion* (edited by Dr. Robert E. D. Clark, Paternoster Press, Ludgate House, Fleet Street, London, E.C.4. 1*s*. 6*d*. per copy), is intended, as the editor says, "to make science cultural; to show how science may strengthen religious belief instead of being allowed to develop independently and unconnected with our deepest needs". It is intended for the general public and particularly the young who learn something about science at school and are eager to know more. The articles in the first two numbers are excellently designed for their purpose. They are short, simply written and informative. Many of them are reviews of recent important books. The subjects include chemistry, biology, anthropology, psychology on the more purely scientific side, also historical and philosophical work. If the present standard can be maintained, the venture deserves to be a success.

Incentives in Industry

The perennial problem of incentives in industry has recently been considered by Prof. C. H. Mace (*Occupational Psych.*, 22, No. 1; January 1948). After agreeing with a recent statement of Nigel Balchin's that the main satisfaction in work will come from making it as enticing as possible, Mace then suggests that an alternative satisfaction will come from making work obligatory, although, as he repeatedly states, all work is complexly motivated. The appeal to obligation is based on the belief that there are, in human nature, forces that impel a man to perform tasks that he finds unpleasant and which he is under no compulsion to perform. In times of crisis the 'emergency response' of the emotions will produce effects but only by a draft on reserves, and Mace suggests that to maintain the will to work at an optimum level will depend upon long-term sources of human motivation. In the professions and the skilled crafts a dominating motive which compels people to stick to their jobs is because they must. They depend upon something being expected of them and upon the sustaining influence of someone's valuation. In jobs which contain little of inherent interest Mace indicates that there should be a more effective use of social pressures by placing responsibility not exclusively on the individual but on the working groups; that is, instead of controlling human energies from above or from within, control should be from around. Scientific study of these problems would afford a new approach to the problem of incentives.

Potato Blight and the Weather in Britain

It would be of considerable advantage if initial outbreaks of potato blight could be forecast with accuracy. This would allow timely application of protective sprays, the value of which is directly proportional to the earliness of effective application. Van Everdingen in Holland has suggested conditions which would herald the first attack by blight, and A. Beaumont has investigated their application to Devon and South Cornwall (*Trans. Brit. Mycol. Soc.*, **31**, Parts 1 and 2; July 1947). The Dutch rules indicated blight in south-west England rather earlier than it appeared, and it has been found that revised conditions gave more accurate forecasts. The conditions are: (1) minimum temperature not less than 50° F., and (2) relative humidity more than 75 per cent for two consecutive days. Mr. Beaumont's suggestions have been available in summary form for some time, and have been tried in other areas. They have given useful forecasts; but in some northern areas of Britain it seems necessary to neglect the earliest forecasts of the season, presumably because blight spores may not be present.

British Museum (Natural History)

A series of exhibits illustrating the "Succession of Life through Geological Time", from the origin of life perhaps a thousand million years ago to the emergence of man within the last million years, has just been opened to the public in one of the geological galleries of the British Museum (Natural History). Each geological period is represented by a small selection of the fossil remains of plants and animals which lived in those times, showing how fossils reflect past conditions, and how the various forms of life developed and reacted on one another in slowly changing environments. The great amount of war damage still to be repaired will make it impossible to open all the geological galleries to the public for some time to come; and in the meantime this new series of exhibits will serve as a general introduction to the study of fossils.

Photocopies of French Scientific Periodicals

It has already been announced that a small French scientific library had been opened at the Institut Français du Royaume-Uni, and arrangements made to obtain on loan microfilms of articles from periodicals not available in the library (see *Nature*, November 15, 1947, p. 669). Since many requests have been received for photocopies in preference to microfilms, the Cultural Counsellor to the French Embassy, with the help of the British Exchange Control, has now arranged a scheme for obtaining microfilm enlargements from France against payment in sterling. Charges will vary according to the size of the enlargement, but for the average periodical page-size (18 cm. × 24 cm.) will be about 1*s.* 4*d.* a page, plus a small charge for postage. All requests for photocopies should be addressed, not to the Institut Français, but to the General Secretary, French Scientific Office, 58 Knightsbridge, London, S.W.1, from whom further details can be obtained.

Frank B. Jewett Fellowships: Awards for 1948–49

The American Telephone and Telegraph Company has awarded Frank B. Jewett fellowships for 1948–49 for research in the physical sciences to the following: Dr. Warren J. Brehm, at present investigating the possible synthesis of lysergic acid at Harvard University; Dr. Ernest M. Grunwald, for the study of the activity of non-electrolytes in certain solvents; Dr. Leon A. Henkin, instructor in mathematics at Princeton University, for research in the application of mathematical logic to the sciences; James A. Jenkins, for research related to topological mapping problems; Robert Karplus, for work on nuclear research at the Institute for Advanced Studies, Princeton; Alvin I. Kosak, research fellow in the chemistry department, Ohio State University, for research in organic chemistry at Harvard University; Dr. Joaquin M. Luttinger, for work on the theory of the superconductive state; Dr. Paul Olum, who received a Frank B. Jewett fellowship for 1947–48, to continue his work in algebraic topology; Richard N. Thomas, for the study of superthermic phenomena in stellar atmospheres.

British Commonwealth Entomological Conference

The Fifth Commonwealth Entomological Conference is to be held in London during July 22–30. There will be several open meetings at which the following subjects will be discussed: (1) insecticides, including recent developments, mode of action, uses and limitations in the field, mechanical appliances, and application from the air; (2) biological control of insects and weeds; (3) estimation of insect populations in the field; (4) recent developments in the control of insects in stored products; (5) tsetse research; (6) Continental quarantine; (7) locusts and grasshoppers. Programmes will be available in due course on application to the Director, Commonwealth Institute of Entomology, 41 Queen's Gate, London, S.W.7.

Congress of Genetics

A Congress of Genetics is to be held at the Centro di Genetica (Istituto Lazzaro Spallanzani), Pavia, during April 2–4. The first two days of the Congress will be devoted to discussions on work carried out at the Centre on cytogenetics and physicopathology respectively; discussions will also be held on general biological problems such as the relationships between embryology and genetics, genetics and chemical biology, physicopathology and genetics and genetics and systematics. The third day will be devoted to a study of genetics in relation to entomology; it is hoped that entomologists will take part in this Congress as well as geneticists and general biologists. Accommodation will be available at the halls of residence of the University of Pavia. Particulars of the Congress can be obtained from Prof. Carlo Jucci, Centro di Genetica (Istituto Lazzaro Spallanzani), Pavia.

Physical Society: Annual Summer Meeting

The annual summer meeting of the Physical Society will be held in Oxford during July 23–24. The main subject will be "Microwave Spectroscopy", including nuclear resonance. In addition, time will be reserved for a discussion on "Helium 3" and other items of topical interest. The Clarendon Laboratory will be open to visitors throughout July 24. Among the speakers will be Dr. B. Bleaney (Oxford), Dr. N. Bloembergen (Leyden), Dr. R. M. Bozorth (Bell Telephone Laboratories), Prof. J. G. Daunt (Ohio State University), Prof. C. J. Gorter (Leyden), Dr. J. H. E. Griffiths (Oxford), Prof. A. G. Hill (Massachusetts Institute of Technology), Dr. C. Kittel (Bell Telephone Laboratories), Prof. R. V. Pound (Harvard), Prof. M. H. L. Pryce (Oxford), Dr. B. V. Rollin (Oxford), Prof. J. C. Slater (Massachusetts Institute of Technology), Prof. J. H. Van Vleck (Harvard). Those wishing to contribute to the Conference discussion should communicate with Prof. F. E. Simon at the Clarendon Laboratory, Oxford. Non-members of the Physical Society wishing to attend should write for further information before April 1 to the Secretary/Editor, Physical Society, 1 Lowther Gardens, Prince Consort Road, London, S.W.7.

Congress of Universities of the British Empire

The annual Congress of Universities of the British Empire will be held at Oxford during July 19–23, and a provisional programme has been issued. The topics for discussion include relationship of the State and the universities; inter-university relations; the balance of research and teaching at universities; structural and moral changes produced in modern society by scientific and technological advance; general plans for Colonial higher education; and the extension of the University Secondment Scheme. Further particulars can be obtained from the Secretary, Universities Bureau of the British Empire, 8 Park Street, London, W.1.

University of London: Appointments

The following appointments in the University of London have been announced: Mr. K. de B. Codrington, keeper in the Indian Section of the Victoria and Albert Museum since 1935, to the University chair of Indian archæology tenable at the Institute of Archæology and at the School of Oriental and African Studies; Prof. E. D. Hughes, professor of chemistry at the University College of North Wales, Bangor, to the University chair of chemistry tenable at University College as from October 1; Mr. Gordon Manley, University lecturer in geography at Cambridge, to the University chair of geography tenable at Bedford College as from October 1.

Special Librarianship

A Study Group on Special Librarianship is being arranged by the Association of Special Libraries and Information Bureaux and will be held at the Library Association, Chaucer House, Malet Place, W.C.1, during April 13–17. The general theme will be "The Compilation of Information in Special Libraries", and the course is designed to help students who have recently started work in such libraries. The programme includes visits to special libraries in London, and lectures by Mr. B. Fullman, information officer of the British Non-Ferrous Metals Research Association; Mr. H. S. Hyland, of the House of Commons Library; Miss A. M. Goodwin, Economic Information Unit of the Treasury; and Dr. W. E. Batten, of I.C.I., Ltd., Plastics Division. Further particulars can be obtained from the Association of Special Libraries and Information Bureaux, 52 Bloomsbury Street, London, W.C.1.

Announcements

The Geographic Society of Sweden has awarded its Vega Medal to Admiral Richard Byrd. This Medal, named after the Swedish *Vega* expedition which, with the Swedish explorer Adolf Erik Nordenskjöld as leader, was the first to sail through the North-East Passage in 1878–80, is awarded annually in recognition of prominent achievements in the field of exploration.

The Manchester and District Branch of the Institute of Physics is arranging a conference, to be held in the Physics Department of the University of Manchester during July 8–10, on "Semiconductors and their Applications". Communications regarding the conference should be sent to Dr. F. A. Vick, Physics Department, University, Manchester 13.

A Conference is being arranged by the Northern Branch of the Association of Special Libraries and Information Bureaux in Leeds during April 2–3. Dr. E. Semister, director of research, Kirkstall Forge, Ltd., will address the opening session on "Research and Information Services for the Metallurgical Engineer and the City Librarian", and Mr. F. C. B. Hutchings will speak on "Training and Practice in Special Librarianship" at the following session; there will be a civic reception in the evening. The morning session on April 3 will be addressed by Mr. Hugh Gaitskell, Minister of Fuel and Power. Visits to the Wool Industries Research Association and the Central Research Department of Brotherton and Co., or to Temple Newsam, complete the programme.

The Ministry of Agriculture and Fisheries invites applications for ten senior scholarships, tenable at university departments of agriculture, or agricultural colleges, for degree or diploma courses in an agricultural subject, or at veterinary colleges for courses in veterinary science; six extended junior scholarships (for those who have already held junior awards), and sixty junior scholarships, tenable at farm institutes or similar institutions, for courses not exceeding one year in duration, in agriculture, horticulture, dairying or poultry husbandry. The scholarships are open to the sons and daughters of agricultural workers and to *bona fide* workers in agriculture. Forms of application, to be returned by April 30, can be obtained from the Secretary of the Ministry, Block 4, Bickenhall Mansions, Baker Street, London, W.1.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications

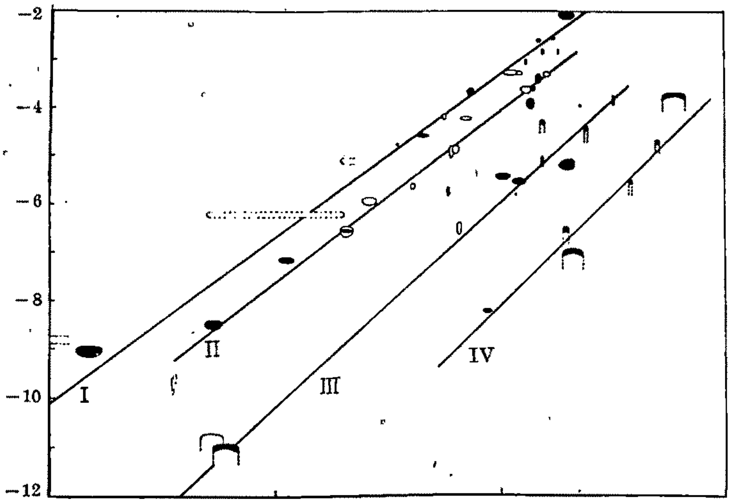
A Revised Sargent Diagram

IN 1938 Dr. Bretscher and I[1] published a Sargent diagram for the 'natural' β-active bodies in a form in which the degree of uncertainty arising from the incomplete state of knowledge at the time was clearly exhibited, and certain 'unobserved' transitions were also represented as in an earlier diagram of Gamow and Teller[2].

Since our first diagram was published, much work has been done on the β-particle spectra of the classical radioelements and many of the previous uncertainties have been resolved; also a great deal of information concerning 'artificially produced' heavy species has accumulated in the interim[3]. Furthermore, various attempts have been made to construct Sargent diagrams covering the whole range of known β-active bodies, both 'heavy' and 'light'[4].

The present note is concerned with the restricted topic of the diagram appropriate to the range of Z (atomic number) from 81 to 93, inclusive: this diagram, containing the newly available information and with outstanding uncertainties represented as before, is given in the accompanying figure. 'Points' are plotted for fifty β-transitions, forty-one 'observed' and nine 'unobserved'. No detailed information is available for possible β-active species with $Z = 86$, 85 or 84, thus the points belong to two groups in Z: twenty-three are for $93 \geqslant Z \geqslant 87$ and twenty-seven for the narrower group having $83 \geqslant Z \geqslant 81$. Of the unobserved transitions, five belong to the group of lower, and four to the group of higher, Z. Points for species with A (mass number) odd are represented by open uncertainty loops; those for species with A even by full loops in the diagram.

Traditionally, two well-defined 'lines' have been recognized on a diagram such as we are discussing, and evidence for lines of higher order has been deduced from the unobserved transitions[2]. Moreover, in recent discussions it has generally been assumed that the well-defined lines correspond to disintegration transitions which are 'allowed' or 'once-forbidden' according to the selection rules of Gamow and Teller[2]. These lines are the lines labelled I and III in the present diagram. A significant fact emerges, however, in that the revised diagram shows quite clearly the presence of another line (II), intermediate between the two lines already recognized, and nearer to the allowed (I) than to the original once-forbidden (III) line. The interpretation of this new line is a matter of interest.



SARGENT DIAGRAM, $80 < Z < 94$. λ IN SEC.$^{-1}$; E IN MEV.

In the first place the suggestion was examined that a doubling of the allowed line was involved, corresponding to the two Z groups of the diagram. This suggestion was rejected after an analysis of the distribution of points on the lines: of the 'points' overlapping line I, four belong to the higher Z group and three to the lower; for line II the corresponding ratio is 4 to 5. Also the separation of the lines ($\Delta \log_{10}\lambda$, $0{\cdot}75$–$1{\cdot}1$) is markedly greater than the separation calculated on the Fermi theory for the extreme values of Z in question. This calculated separation (Z, 93–81) is practically constant ($\Delta \log_{10}\lambda$, $0{\cdot}3$) over the whole energy-range from $0{\cdot}3$ to 3 MeV.

It was therefore assumed, tentatively at least, that a revision of the assignment of orders of forbiddenness was required, the new line (II) representing once-forbidden and line III twice-forbidden transitions according to the Gamow–Teller rules. This revision brings certain definite advantages. Here it will be sufficient to mention the β-disintegration of radium E, which now becomes twice-forbidden. Hitherto, it has been difficult to explain the form of the energy spectrum in this case on the assumption that the transition is once-forbidden only[5]. Other cases will be discussed in greater detail in due course[6].

While the reassignment of order, above described, is definitely put forward as the most probable interpretation of the revised diagram, one further possibility should be mentioned. Itoh[4] has directed attention to a feature of the Sargent diagram for the lightest of the artificially radioactive species (positron- and electron-active) which in its empirical aspect is entirely similar to the feature discussed here. He distinguishes four lines on this diagram at the following intervals of $\log_{10}\lambda$, namely, $\Delta \log_{10}\lambda \sim 1{\cdot}5, 2{\cdot}4, 2{\cdot}5$, respectively. It might appear tempting to identify this structure with the structure of the diagram given in this note. But Itoh gives reasons for supposing that his first line represents 'super-allowed transitions' in respect of the Gamow–Teller classification—or, in the sense of the Wigner[7] theory of the symmetry properties of nuclear states, the only 'truly allowed' transitions, those involving initial and final states belonging to the same symmetry multiplet. Such transitions, according to this theory, would not be expected except when the change in isotopic number in the transition is $(1) \leftrightarrow (-1)$, or in certain cases $(2) \leftrightarrow (0)$, and this condition limits present knowledge of transitions of this type to the mass range $A < 43$.

A final point might be made in this preliminary discussion. It is that there is a very noticeable concentration of the points for A odd on the Sargent lines I and II. Out of eighteen points for A odd, only two fall significantly below line II, whereas there are eighteen points for A even below this line. Similarly, all the points on or below line IV (five 'unobserved' points and the representative point for the 3·5yr. $^{204}_{81}$Tl) are for A even (and Z odd). It would appear that very frequently there is a large difference of spin between the ground-states of initial and final nuclei in these latter cases. This conclusion is not surprising when it is realized that the neutron and proton numbers change from the $\begin{pmatrix}\text{odd}\\\text{odd}\end{pmatrix}$ to the $\begin{pmatrix}\text{even}\\\text{even}\end{pmatrix}$ configuration in such transitions.

Electron Tracks in Photographic Emulsions

PHOTOGRAPHIC emulsions have been used to an increasing extent for the recording of nuclear tracks passing through the sensitive layer, in particular by Dr. C. F. Powell and his collaborators[1], and by Demers[2]. Particles of relatively high ionizing power such as alpha-particles and protons give well-defined tracks; those of lesser ionizing power, such as mesons, yield rather tenuous tracks; while electrons do not as a rule produce recognizable tracks in the emulsions available so far, although Demers[2] claims to have seen electron tracks on one of his emulsions.

A new emulsion has recently been evolved in the Kodak Research Laboratories which is sufficiently sensitive to enable electron tracks to be recorded unmistakably.

The emulsion was tested for proton sensitivity by bombardment with neutrons from a radium – beryllium source, with a 17-cm. thickness of lead interposed between the plates and the source to diminish the gamma-ray intensity incident on the sensitive material. Microscopical examination of the plates after processing showed that the background to the proton tracks was of a much more heterogeneous nature than was obtained with exposures to a pure alpha-ray emitter, for example, polonium.

Under high magnification, this heterogeneous background was seen to consist of numerous fairly short, highly curved chains of developed grains. It is believed that these are the low-energy ends of tracks due to photo-electrons and recoil electrons liberated by gamma-rays. Electrons, being particles of low mass and low ionizing power, might be expected to produce just such types of tracks in a photographic emulsion, which remind one strongly of similar tracks obtained in a cloud chamber.

Since they are highly curved, very few of these tracks are in one plane, and satisfactory photomicrographs are therefore difficult to obtain. Figs. 1 and 2 are photomicrographs (× 2,000) showing the type of track obtained. Fig. 3 is a photomicrograph at the same magnification of a plate exposed to light to give approximately the same average grain density as the gamma-ray exposure.

I should like to acknowledge the co-operation of Mr. D. H. Perkins of the Imperial College of Science and Technology, London, and my colleagues in this Laboratory in the evolution of this emulsion.

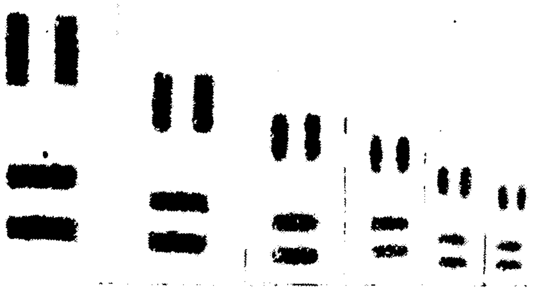
Resolution Testing in Autoradiography

THE resolution obtainable in autoradiographs has so far been estimated[1] by the sharpness obtainable when photographic emulsions are exposed in contact with biological sections in which radioactive isotopes have been deposited by biochemical processes. The distribution of the radioactive isotope will, however, vary from one specimen to another, and T. C. Evans[2] points out that even successive sections from the same specimen will not be absolutely identical. Strict comparisons of the resolution given by different techniques or photographic emulsions are thus most difficult to make.

Preliminary tests showed that a photographic silver image on a material such as the Kodak Maximum Resolution plate could be converted successively to silver bromide and silver iodide and still give a line separation of 0·5 μ. These reactions can therefore be used to give a deposit of I^{131} with any required distribution, thus forming a radioactive test chart. Such test charts were made by applying about 0·01 c.c. of a solution of I^{131} (supplied by the Medical Research Council) to an area 2 mm. × 2 mm. of the emulsion surface containing a resolution test image which had previously been converted to silver bromide. Fig. 1 shows a photomicrograph of some of the units of the original test chart image, the units from *A* to *F* representing line separations of respectively 4·5 μ, 3·7 μ, 3·0 μ, 2·5 μ, 2·0 μ and 1·7 μ. After washing and drying, a 4-μ thick coating of a highly concentrated 'fine-grain emulsion, prepared in these laboratories for the recording of nuclear tracks[3], was transferred to the surface of the test chart, as described by S. R. Pelc[1]. After the 'exposure', the emulsion-coated test chart was soaked in water for a few minutes, and the emulsion layer was processed in the stripped condition. Fig. 2 shows the autoradiograph images corresponding to Fig. 1. In the original autoradiograph it is apparent that useful resolution is obtained with 2·5 μ (*D*) and perhaps even with 2·0 μ (*E*) separation, but not with 1·7 μ (*F*).



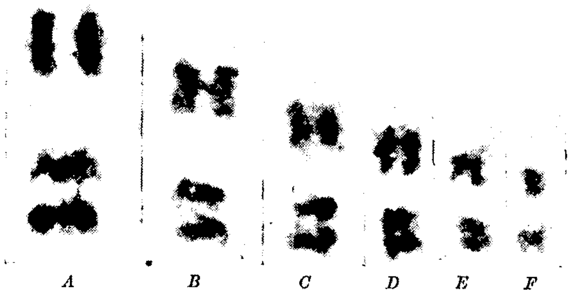


Fig. 1 (above). PHOTOMICROGRAPH (× 700) OF IMAGE FROM ORIGINAL TEST CARD
Fig. 2. IMAGES OF AUTORADIOGRAPH (× 700) CORRESPONDING TO FIG. 1

It would seem that such test charts could be employed for systematically estimating the relative importance of the various emulsion and geometrical factors influencing the resolution of autoradiographs. They might also be used for comparing the effect of electrons of varying energy given by different isotopes. Another possibility is the production of test charts made from microphotographic replicas of tissue sections to aid in the interpretation of autoradiographs made from biological material.

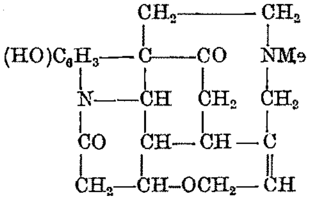
Relation of Vomicine to Strychnine and Brucine

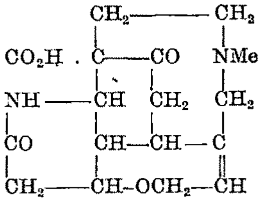
VOMICINE, $C_{22}H_{24}O_4N_2$, a congener of strychnine, $C_{21}H_{22}O_2N_2$, has been investigated by Wieland and his collaborators; but no precise connexion between the alkaloids has yet been disclosed, though many reactions and transformations suggest the close similarity of their molecular structure. On oxidation with chromic acid[1], vomicine yields an acid, $C_{17}H_{22}O_5N_2$, $3H_2O$, which characteristically loses carbon dioxide at 130°, affording a base, $C_{16}H_{22}O_3N_2$. We have now found that the same acid can be obtained by oxidation of N-methyl-*sec*-pseudostrychnine, or better, N-methyl-*sec*-pseudobrucine, by means of chromic acid. The identity has not yet been confirmed by direct comparison*; but there can be little doubt of it from the analyses ($3H_2O$), rotatory power, melting points, and behaviour on heating. The resulting base has the composition, melting point and crystalline form recorded for the product from vomicine.

This result establishes that vomicine is to an *ar*-hydroxystrychnine as N-methyl-*sec*-pseudostrychnine is to strychnine. The probability of this outcome was suggested in a letter from one of us to Prof. Wieland in 1939, and the theory has been mentioned on several occasions since that time. The proof of it which is now available enables us to make use of other aspects of vomicine chemistry, which become directly applicable to the strychnine problem.

Thus the ready formation of the base, $C_{16}H_{22}O_3N_2$, already mentioned, is a clear indication of the site of a carbonyl group in N-methyl-*sec*-pseudostrychnine, and affords strong support to the formulæ advanced on other grounds. In illustration, (I) and (II) represent vomicine and the acid $C_{17}H_{22}O_5N_2$, respectively; (II) is seen to be a β-keto-acid, probably stabilized as $CO_2^- - \ddot{C} - \dot{C}(OH) - \dot{N}Me^+$.



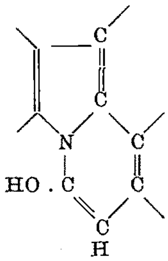
(I)



(II)

The formation of such a betaine is doubtless facilitated by the cyclization which it implies, and explains why (II) is capable of existence under the conditions of its manipulation.

R. B. Woodward and his collaborators[2] have recently suggested, on the basis of ultra-violet spectra, that Leuchs' 'strychnone' obtained by the action of hydrogen peroxide on pseudostrychnine is a true indole derivative. We have reached the same conclusion by a study of the brucones[3]. These have the composition of oxobrucines; the isomeride, m.p. 310°, is a by-product in the preparation of pseudo-brucine; that of m.p. 180° is obtained by action of hydrogen peroxide on pseudobrucine. The former shows normal brucine reactions and probably contains : $N(b).CO{-}\overset{|}{C}{=}CH{-}$, but the latter (m.p. 180°) exhibits



(III)

a unique series of colour reactions and is probably an aromatic indole. It is the only brucine derivative we have encountered which does not give a related cacotheline on treatment with nitric acid. The product, described by Leuchs *et al.*[3] as such, is actually a simple nitro-derivative which has also suffered hydrolysis of : N . CO —, probably : N(*a*) . CO ., to : NH CO$_2$H . .

The intense green fluorescence and yellow-coloured solutions often obtained from strychnine derivatives (and easily from the above brucone) by the action of alcoholic alkalis is attributed to the formation of the structure (III).

The *C*/*D* Ring Union in Œstrone and Equilenin

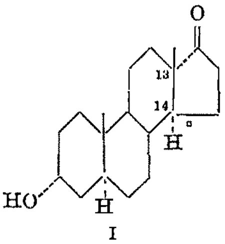
The method of molecular rotation differences which has been applied to other steroid structural problems by Barton[1] throws some light on the nature of the *C*/*D* ring union in œstrone and equilenin recently discussed by Shoppee[2,3] and by Heer and Miescher[4,5]. The evidence thus obtained, which is given below, when combined with that collected by Shoppee[3], indicates that (+)-equilenin and probably (+)-œstrone have the same configuration at the *C*/*D* ring union as the androgens, bile acids and sterols. The data available are few, and the conclusions are therefore drawn with reserve.

Configuration at C$_{13}$. Butenandt and co-workers[6,7] obtained by irradiation of (+)-œstrone and androsterone *lumi*-compounds, which are epimeric at C$_{13}$ with the starting materials. The molecular rotations (M_D) of these compounds and the differences (Δ) between them are as follows (all rotations given in this letter were measured at *c.* 20° for the sodium *D* line except that marked *, which is for 5461 A.):

A = ETHANOL, *C* = CHLOROFORM, *D* = DIOXAN

	Solvent	M_D (Natural)	M_D (*Lumi*)	Δ (*Lumi*—natural)	Refs.
Androsterone	*A*	+275	−290	−565	7,8
Œstrone	*D*	+458	−116	−574	6,9
Œstrone methyl ether	*C*	+486*	−80	−566	6,10

Clearly the change in configuration from 'natural' (+)-œstrone to *lumi*-œstrone is the same as that from 'natural' androsterone to *lumi*-androsterone; 'natural' (+)-œstrone therefore has the same configuration at C$_{13}$ as 'natural' androsterone [I] and all the other 'normal' steroids which are related to it. The work cited by Shoppee[3] shows conclusively that (+)-œstrone and (+)-equilenin have the same configuration at C$_{13}$; (+)-equilenin is therefore a 13-*n* compound.



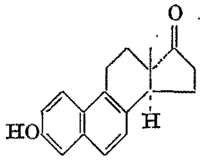
I

Configuration at C$_{14}$. Recent work by Plattner, Ruzicka, Heusser, Pataki and Meier[11] on 14-*iso* compounds permits the calculation of $\Delta_{14} = M_D(14\text{-}iso) - M_D(14\text{-}n)$.

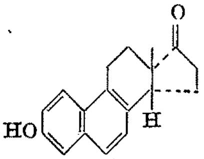
	Solvent	M_D (14-*n*)	M_D (14-*iso*)	Δ_{11}	Refs.
17-*iso*-*allo*-ætio-cholanic acid methyl ester	*D*	−130	+83	+213	11,12
3(*β*)-acetoxy-17-*iso*-ætio-cholanic acid methyl ester	*C*	−105	+109	+214	11,13

The molecular rotations of the four equilenins (in dioxan) are as follow[14]:

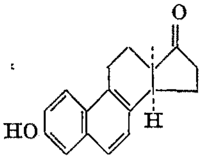
(+)-*iso*-equilenin	+391	(−)-*iso*-equilenin	−391
(+)-equilenin	+224	(−)-equilenin	−224



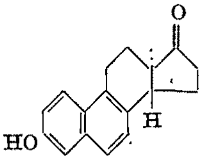
II. 13-*n*, 14-*n*



III. 13-*n*, 14-*iso*



IV. 13-*iso*, 14-*n*



V. 13-*iso*, 14-*iso*

These four compounds must between them have the formulæ II–V. From the evidence given above (+)-equilenin must be II or III. Four hypotheses can be made and tested by the molecular rotation difference method, namely:

A (+)-equilenin is II; (+)-*iso*-equilenin is III.
B ,, ,, II; ,, IV.
C ,, ,, III; ,, II.
D ,, ,, III; ,, V.

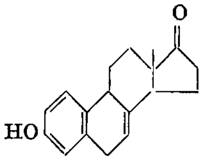
The Δ-values found above for compounds of known structure, and those calculated from the rotations of the equilenins on each of these hypotheses, are given in the following table.

		Δ_{13}	Δ_{14}
Found for compounds of known structure		−565	+214
Calculated from equilenins; hypothesis	*A*	−615	+167
,, ,, ,, ,,	*B*	+167	−615
,, ,, ,, ,,	*C*	−615	−167
,, ,, ,, ,,	*D*	+167	+615

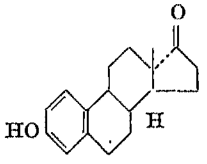
Clearly the only tenable hypothesis is *A*. Thus (+)-equilenin has the formula II, with the same *trans* *C*/*D* ring union as is present in the androgens, bile acids and sterols.

(+)-*iso*-Equilenin is therefore 14-*iso*-equilenin [III]. Chemical evidence for the correspondence of (+)-equilenin and (+)-*iso*-equilenin at C$_{13}$ is also available; (+)-equilin [VI] was converted by Dirscherl and Hanusch[15] into (+)-equilenin and indirectly into (+)-*iso*-equilenin by Hirschmann and Wintersteiner[16] in conditions in which epimerization at C$_{13}$ was most unlikely.

The evidence cited by Shoppee[3] for the stereochemical correspondence of (+)-œstrone and (+)-equilenin is not quite as convincing for C$_{14}$ as it is for C$_{13}$, since epimerization at C$_{14}$ might perhaps have occurred during the dehydrogenation of (+)-equilin [VI].



VI



VII

It is, however, very probable that (+)-œstrone has the 'normal' *trans C/D* ring union as shown in VII.

I have studied the molecular rotations of the doisynolic and marrianolic acids and of their bis-dehydroderivatives[4,5,17] in the hope of obtaining some evidence as to their configurations. The results give no indication in favour of any of the possibilities discussed by Shoppee[2] or by Heer and Miescher[4,5], and show the need for restraint in applying the method of molecular rotation differences, valuable though it is in dealing with certain groups of closely related substances. However, the evidence for a *trans C/D* ring union in (+)-œstrone and (+)-equilenin given in Shoppee's letter[3] and the present communication strongly supports the scheme outlined by Heer and Miescher[5] (at p. 553).

I am indebted to Dr. C. W. Shoppee for sending me a copy of his letter[3] before publication.

p-Aminosalicylic Acid in the Treatment of Tuberculosis

The preliminary communication of Lehmann[1] on the treatment of human tuberculosis with *p*-aminosalicylic acid led us to undertake a detailed study of this acid. *p*-Aminosalicylic acid[2] is obtained by the reduction of *p*-nitrosalicylic acid, which itself can be prepared by a variety of methods[3]. These methods are uniformly laborious and we have consequently investigated alternative methods for its preparation. We find that direct carboxylation of *m*-aminophenol, using modified Kolbe conditions, gives *p*-aminosalicylic acid and not *p*-hydroxyanthranilic acid[4].

Clinical experience with the acid, which will be described in detail elsewhere, has amply confirmed and extended Lehmann's findings and has shown that the acid, which is well tolerated by man, is markedly effective in the treatment of pulmonary tuberculosis and of tubercular empyæma. A series of functional derivatives of the acid has been prepared, some of which are extremely active *in vitro* against the $H_{37}RV$ strain of *M. tuberculosis*.

A Modified Technique in Filter-Paper Chromatography

Various adaptations of filter-paper to chromatography have been published[1–4]; the following technique has advantages of simplicity of apparatus, speed, reproducibility, and particular suitability for micro-analysis. (Sensitivity approximately 2 micrograms solute.)

Two parallel cuts, about 2 mm. apart, are made from the same edge up to the centre of an 11-cm. circular filter-paper, and the 'tail' so formed, after bending at the joint perpendicular to the plane of the paper, and cutting down to approximately 1½ cm., is immersed in the solution under analysis, contained in a capsule inside a Petri dish, which supports the filter-paper. A glass plate prevents evaporation.

By capillarity, the solution rises up the 'tail' and spreads circularly outwards. (Alternatively, the solution may be pipetted on.) The paper is then removed, and the 'tail' immersed in developing liquid, rate of development being controlled by tail-width and height of paper above liquid surface. Coloured solutions suitably developed give sharp separation of coloured rings.

In the case of colourless chromatograms, after development, a test sector is cut out and pressed between filter-papers impregnated with reagents giving coloured products with constituents of the chromatogram. Preparation of derivatives on the main chromatogram, which may be undesirable, is thus avoided.

Another method is based on the variation in rate of charring of the paper, caused by adsorbed substances: bands may frequently be detected by holding a test sector above a heated bunsen gauze.

After marking their positions on the main chromatogram and drying, the various bands may be cut out and conveniently eluted by placing both ends of each curved strip on filter-paper soaked in eluent. Capillary action concentrates the adsorbate in the centre of the strip, whence it may be drawn off on paper or by capillary pipette.

A study of modified types of filter-paper in particular separations will be discussed more fully elsewhere.

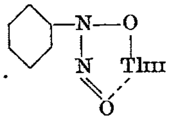
Inner-Complex Salts of Trivalent Thallium

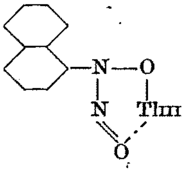
HITHERTO it has seemed that thallium was the only heavy metal with but slight tendency to form water-insoluble normal and inner-complex salts with organic compounds of acid character. Monovalent thallium gave insoluble salts with the mercaptans thioglycollic acid-anilid, thioglycollic acid-β-aminonaphthalid ('Thionalid')[1] and mercaptobenzthiazole[2]. Of these compounds only the first and second can be considered as inner-complex salts. Since thallium belongs to the same group in the Periodic Table as the inner-complex-forming metals gallium and indium, the existence of inner-complex salts of trivalent thallium was to be expected; and it has now been found that inner-complex salts of trivalent thallium with nitrosophenylhydroxylamine, α-nitrosonaphthylhydroxylamine, 8 hydroxychinoline, 5,7 brom-8 hydroxychinoline and 'Thionalid' can be obtained in the following manner.

Sufficient tartaric acid, citric acid or sulphosalicylic acid is added to a solution of thallium (Tl III) sulphate, bromide, etc., in order to avoid, by formation of complex thallic ions, precipitation after addition of ammonia. To the ammoniacal solution thus obtained, a solution of the complex-forming organic compound in alcohol or ammonia is added. Immediately precipitates of the respective thallic inner-complex salts are formed. The precipitations are quantitative, as in the filtrates no thallium can be detected by the usual tests.

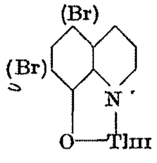
Precipitates with nitrosophenyl- and nitrosonaphthyl-hydroxylamine (white amorphous products) are also obtainable from mineral acids, non-masked thallic solutions. In this case the precipitate is mixed with the precipitant. The precipitates with 8-hydroxychinoline and 5,7 brom-8 hydroxychinoline (orange-coloured crystalline products) can also be formed from non-masked, acetate-buffered thallic solutions with alcoholic solutions of the reagents. The composition and constitution of the above inner-complex salts correspond to co-ordination formulæ I–III.



I

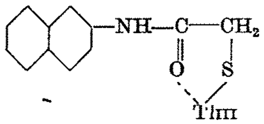


II

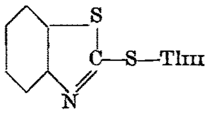


III

The precipitation with 'Thionalide', from ammoniacal-masked thallic solution, is white, whereas thallous 'Thionalid' is yellow. When precipitated with mercaptobenzthiazole, a yellow product (thallic compound) is formed, which in a few minutes is transformed into white thallous mercaptobenzthiazole and the disulphide of the mercaptan. The different behaviour of mercaptobenzthiazole and 'Thionalid' is obviously based on the fact that only the latter forms an inner-complex salt with trivalent thallium. Through chelate-ligation (IV) the trivalent thallium as well as the oxidizable mercaptan are stabilized. In the case of the normal mercaptobenzthiazole-salt V there is no stabilization by chelate-ligation, and therefore a redox reaction occurs, forming thallous mercaptobenzthiazole and the disulphide of the mercaptan.



IV. Stable inner-complex salt



V. Unstable normal salt

It seems that certain inner-complex salts of trivalent thallium can serve as a basis for new methods for the detection and determination of thallium.

Order of Stability of Metal Complexes

IN a recent communication[1] it was pointed out that the order of stability of a series of internal metal complexes is substantially the same whether the metals are combined with bidentate chelate molecules like salicylaldehyde, glycine or 8-hydroxyquinoline. There is evidence from the results of other workers[2,3] that the same order is to be found with complex cations and with internal complexes formed with quadridentate chelate molecules. Cations containing ethylenediamine have been studied by Bjerrum[2,4] and Carlson, McReynolds and Verhoek[3]. From the accompanying table, which shows the overall stability constants for salicylaldehyde and ethylenediamine complexes, the similarity of order in the two cases is evident.

Bivalent Metal	log K_{sal}	log K_{en}
Pd	14·8	26·9(*a*)
Cu	13·3	19·6(*c*)
Ni	9·2	18·6(*b*), 18·1(*c*)
Co	8·3	13·8(*b*)
Zn	8·1	12·9(*d*), 12·1(*c*)
Cd	7·8	12·3(*d*), 12·1(*c*)
Fe	7·6(*a*)	9·5(*b*)
Mn	6·8(*a*)	5·7(*b*)
Mg	6·8	—

Abbreviations: sal = salicylaldehyde; en = ethylenediamine. (*a*) Recent measurements by the authors; (*b*) measurements by Bjerrum, ref. 2; (*c*) measurements by Carlson, McReynolds and Verhoek, ref. 3; (*d*) measurements by Bjerrum and Anderson, ref. 4. The figures for Cu and Pd in the right-hand column refer to complexes containing two molecules of ethylenediamine; all the other metals listed combine with three molecules of ethylenediamine.

If one metal complex is more stable than another of the same type, we should expect to find that, under suitable conditions, a metal will displace another from a less stable complex. By means of such displacement reactions, Pfeiffer, Thielert and Glaser[5] have investigated the relative stability of compounds formed with *bis*-salicylaldehyde-ethylenediimine. From a systematic study of reactions carried out in pyridine solution, Pfeiffer and his collaborators place the metals in the following order:

$$\mathrm{Cu^{II}} > \mathrm{Ni^{II}} > \mathrm{Fe^{III}} > \mathrm{Zn^{II}} > \mathrm{Mg^{II}}$$

which, with one exception, is identical with the order in the table. That iron appears in a different position is almost certainly due to the fact that here we are dealing with $\mathrm{Fe^{III}}$, whereas the other comparisons (in table) deal with $\mathrm{Fe^{II}}$.

Owing to the fact that the reactions were carried out in pyridine solution, they are more appropriately regarded as exchange reactions, because the displacing metal is already in the form of a pyridine-containing complex ion. A typical reaction is:

$$[\mathrm{Cu(py)_6}]^{++} + [\mathrm{Ni(sal\text{-}en)}] \rightleftarrows [\mathrm{Cu(sal\text{-}en)}] + [\mathrm{Ni(py)_6}]^{++}, \quad . \quad (1)$$

where sal-en = *bis*-salicylaldehyde-ethylenediimine and py = pyridine. This point of view introduces a further complication in so far as the reaction would seem, at first sight, to show that the copper pyridine complex is less stable than the nickel pyridine complex, an order that would not be expected from the table. This raises the question: In what circumstances is one justified in drawing conclusions about relative stability from experiments of this kind?

It may be shown that the equilibrium constant, K_1, for reaction (1) can be expressed in terms of the overall stability constants of the different complexes involved. Thus

$$K_1 = \frac{[\mathrm{Cu(sal\text{-}en)}]\ [\mathrm{Ni(py)_6}]^{++}}{[\mathrm{Ni(sal\text{-}en)}]\ [\mathrm{Cu(py)_6}]^{++}} = \frac{K_{\mathrm{Cu(sal\text{-}en)}} \times K_{\mathrm{Ni(py)_6^{++}}}}{K_{\mathrm{Ni(sal\text{-}en)}} \times K_{\mathrm{Cu(py)_6^{++}}}}$$

It has been observed[5] that reaction (1) goes practically quantitatively from left to right, which means that $K_1 \gg 1$. Under these conditions, we can then be certain that $K_{\mathrm{Cu(sal\text{-}en)}} > K_{\mathrm{Ni(sal\text{-}en)}}$ only if $K_{\mathrm{Cu(py)^{++}}} > K_{\mathrm{Ni(py)^{++}}}$. If, on the other hand, $K_{\mathrm{Ni(py)^{++}}} > K_{\mathrm{Cu(py)^{++}}}$, the relation between $K_{\mathrm{Cu(sal\text{-}en)}}$ and $K_{\mathrm{Ni(sal\text{-}en)}}$ is, from these observations alone, indeterminate. Pfeiffer *et al.* did not take into account the effect of the relative stability of the different pyridine complexes. We have therefore measured the stability constants of the pyridine complexes of copper and nickel, and have found that the copper complex is the more stable.

Although the co-ordination number (n) of $\mathrm{Cu^{II}}$ and $\mathrm{Ni^{II}}$ is frequently four, complex formation curves[2] indicate that as many as six pyridine molecules may be attached to the metal ions in solutions containing a large excess of pyridine. Approximate values of log K, where K is the overall constant, calculated on the assumption that $n = 6$, are 10·2 and 9·8 for the pyridine complexes of copper and nickel respectively. The chief uncertainty in the values of log K arises from the difficulty of measuring the constants for the last steps in complex formation. They are, however, sufficiently accurate to validate Pfeiffer's conclusions about the relative stabilities of the copper and nickel complexes of *bis*-salicylaldehyde-ethylenediimine.

Although it is not yet clear what determines the order of the metals in the series, it is perhaps worth noting that metals forming dsp^2 bonds ($\mathrm{Pd^{II}}$ and $\mathrm{Cu^{II}}$) head the list. So far as the extreme members of the series are concerned, there is a hint that the basicity of the metal may have something to do with stability (the more basic the metal, the less stable its complexes); but owing to the difficulty of assigning numerical values to the basicity of metals[6], no definite statement relating the two factors is possible at present.

We are indebted to Mr. M. L. Hammond for assistance with measurements on the pyridine complexes.

Polarographic Determination of the Gamma-Isomer of Benzene Hexachloride

WE have found that, of the four known isomers of benzene hexachloride, only the gamma is reduced at a dropping mercury electrode. The insecticidal activity of benzene hexachloride is preponderantly due to the gamma-isomer, so that a method of determining the latter is of value in the analysis of benzene hexachloride and insecticidal compositions based on it. This property of the gamma-isomer, which was first discovered by us in 1945, permitted the development of a reliable analytical procedure. Keller *et al.*[1] showed in 1946 that benzene hexachloride gave rise to a polarographic wave, but did not specifically indicate that the wave was due to the gamma-isomer.

This is the sole instance known to us of only one isomer of a substance being reduced at the dropping mercury electrode, and is considered to be due to the polar structure of the gamma-isomer molecule[2].

The wave obtained is not quite a normal one as it appears to involve the progressive reduction, without a break, of three of the chlorine atoms in the molecule. This results in an extended rise in the current-voltage curve over the comparatively wide potential range of − 1·15 to − 1·55 volts *v.* sat. calomel electrode. Buffering at pH values lower than 7 is without effect on the slope of the wave; the latter is reproducible under standard conditions.

The residual and diffusion currents of the wave both exhibit an appreciable rise due to the presence of traces of other reducible materials in the crude benzene hexachloride. This rise in the residual and diffusion currents necessitates the use of an intersection method for the measurement of the wave height.

The conditions of solvent and base electrolyte which have been found to give the best waves are as follows:

Base solution:	Equal volumes of absolute alcohol and distilled water, containing 1 per cent of potassium iodide as electrolyte and 0·005 per cent of gelatin as maximum suppressor. Before recording, dissolved oxygen is removed from solution by a stream of hydrogen or nitrogen.
Recording range:	$-0\cdot6$ to $-2\cdot0$ volts *v.* sat. calomel electrode. The half-wave potential is $-1\cdot35$ volts *v.* sat. calomel electrode.
Concentration range:	0·005 to 0·04 per cent of gamma-isomer in the base solution.
Galvanometer sensitivity:	1/10 to 1/50 of full sensitivity using moderate damping. (Cambridge Instrument Co., Ltd., polarograph.)

Calibration is carried out by subjecting known concentrations of the pure gamma-isomer to a similar procedure and plotting the resulting wave heights against gamma-isomer concentrations. A straight-line curve is obtained which, when extrapolated to zero concentration, gives a small blank corresponding to a small residual current.

Absolute alcohol has been found preferable for the preparation of solutions, as reducible impurities present in the industrial solvent are liable to cause interference.

Size of the Brain in the Ape-Man, *Plesianthropus*

THOUGH the brain of the young *Australopithecus* is about 500 c.c. and that of the adult perhaps 600 c.c. or more, the brain of the type *Plesianthropus* about 450 c.c., and of the beautiful female skull about 415 c.c., it has been suspected that some male brains may have been very much larger. The Kromdraai skull has a brain that we estimated may have been about 650 c.c.; but with little more than the temporal bone and the middle line as evidence the determination is not as convincing as one would like.

Recently we found an imperfect skull at Sterkfontein (skull No. 8) which has much of the top of the brain case and the nearly perfect base. Though the front of the frontal region is lost, we have part of one orbit preserved, and can restore the whole brain with considerable confidence. We give a side view of the brain as we restore it (Fig. 1). This restoration gives us a brain of about 530 c.c.

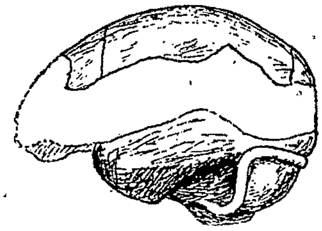

Fig. 1. RESTORED BRAIN OF *Plesianthropus transvaalensis* BROOM, SKULL NO. 8; CAPACITY, 530 C.C. 1/3 NATURAL SIZE

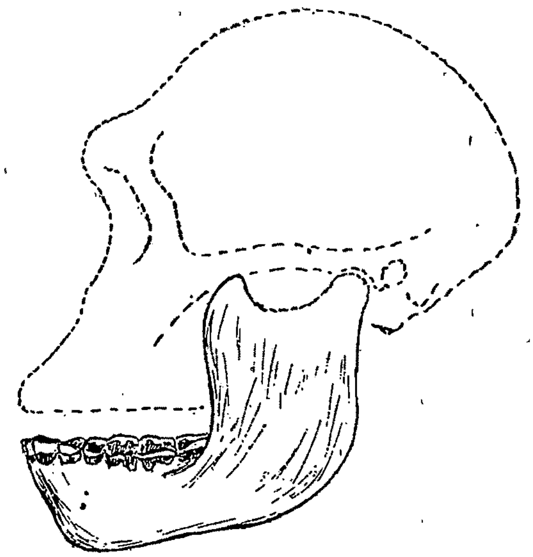

Fig. 2. SIDE VIEW OF MANDIBLE OF MALE *Plesianthropus transvaalensis* BROOM, WITH THE SKULL RESTORED IN OUTLINE. 1/3 NATURAL SIZE

Six months ago we discovered the very fine mandible of a large male. A preliminary account appeared in *Nature* of August 2, 1947. As the jaw is manifestly a male jaw and very much larger than must have been the jaw of the perfect female skull (No. 5), we said: "the male skull that belonged to this jaw must have had a brain of 600 c.c., or perhaps even 700 c.c.". Further development of the jaw shows that it was even larger than suspected. The right ascending ramus is nearly complete though crushed, and shows that it was broader than we had restored it. It is even broader than that of the Heidelberg jaw and much higher.

In skull No. 8, which has the 530 c.c. brain, the measurement from the base of the crown of the third upper molar to the back of the glenoid cavity is 63 mm. The skull belonging to this large mandible must have had a corresponding measurement of about 94 mm. It thus seems probable that the brain belonging to this large jaw had a capacity of well over 700 c.c. and perhaps more than 750 c.c.

From the collection of *Plesianthropus* skulls we now have, it is manifest that there is a very great degree of variation not only in size but also in structure; but as all have been found in a space of about 120 cubic yards, it seems highly probable that all belong to one species. Perhaps we may be right in assuming that the female brains vary from 400 to 600 c.c., and male brains from possibly 600 c.c. to perhaps more than 750 c.c.

We know that *Plesianthropus* had a pelvis that was essentially human, and we can be sure that it walked on its hind feet and used its hands for the manipulation of tools and weapons. If some of the males had brains of perhaps 750 c.c., we can say with confidence that, if *Plesianthropus* was not quite human, it was nearly human.

Nicotinic Acid in Human Blood Cells at Birth

THE nicotinic acid was determined in blood from the umbilical cord, and in blood taken from the mother at the time of birth. The cord blood was obtained by allowing the placental end of the cord to drain into a centrifuge tube containing a mixture of ammonium and potassium oxalates, and the blood was mixed with the oxalates as gently as possible to prevent hæmolysis. The maternal blood was taken from the antecubital vein a few minutes later and mixed with the oxalates in a similar way. The cells were separated by centrifuging the blood for 45 min. at 3,000 r.p.m. and the nicotinic acid was determined in the cell mass by the method of Klein, Perlzweig and Handler[1].

The following results were obtained :

Subject	Nicotinic acid (μgm./c.c. of cells) Maternal blood	Cord blood
A	13·5	12·0
B	12·8	13·4
C	16·2	15·1
D	12·2	12·6
E	12·8	13·0
F	13·0	13·3
G	10·6	12·3
Average	13·0	13·1

No consistent difference was found in the concentration of nicotinic acid in the two kinds of cells. The average concentrations were in the range usually accepted as normal for the blood cells of adults.

The work of Lwoff, Morel and Digonnet[2], who used the *Proteus* technique for their estimations, suggested that the newborn child did not possess any large store of nicotinic acid. These investigators even went so far as to say that the tissues of the infant probably contained smaller concentrations than the same tissues of the mother; but the evidence for this statement was not conclusive. Blood was not investigated, and the present work perhaps throws some doubt on the accuracy of the previous observations, which, as Clements[3] has pointed out, certainly need confirmation.

Human breast milk is a comparatively poor source of nicotinic acid, and the newborn child may need more than it can obtain from this source. If so, it may be able to synthesize the vitamin from tryptophane (Sarett and Goldsmith[4]), or it may have to rely on bacterial synthesis in the gut. An attempt is being made to find out whether such synthesis occurs, and if so, how soon it begins.

This work is being carried out at the Landesfrauenklinik, Wuppertal, through the courtesy of the director, Prof. A. Anselmino, and with his very helpful co-operation.

Effect of Removal of Neurosecretory Cells in the Brain of Adult *Calliphora erythrocephala* Meig.

IN a number of insects neurosecretory cells have been found in the brain[1]; but very little is known of their function. Wigglesworth[2] showed that in *Rhodnius* the moulting hormone is produced by the pars intercerebralis of the protocerebrum, in which part of the brain Hanström[3] had detected neurosecretory cells. Recently, C. M. Williams[4] has found that neurosecretory cells in the brain of *Platysamia cecropia* play an important part in the regulation of the pupal diapause. (I am indebted to Prof. Williams for permitting me to quote this result.)

In the adult insect, the corpus cardiacum and probably the corpus allatum are innervated from the pars intercerebralis of the protocerebrum. In *Leucophæa* (*Blattaria*) B. and E. Scharrer[1] found that colloid could be traced from the secreting nerve cells in the pars intercerebralis to the corpora cardiaca all along the nervus corporis cardiaci. This morphological evidence renders it highly probable that the neurosecretory cells of the brain in some way influence the function of the corpus cardiacum and possibly that of the corpus allatum.

In *Calliphora*[5–8], as in several other insects, the presence of the corpus allatum was found to be necessary for the production of yolk in the egg. If the neurosecretory cells of the brain influence the function of the corpus allatum, it might be expected that removal of these cells would have an effect similar to that of allatectomy.

Owing to their light-bluish colour, the neurosecretory cells in the pars intercerebralis of the protocerebrum can be distinguished in the living *Calliphora*. The neurosecretory cells were removed from forty-nine *Calliphora* females five to eight hours old (at 25° C.) ; thirty-nine flies of the same age served as operated controls. The flies were fed on meat, sugar and water for seven days (25° C.) before they were dissected. The length of the biggest egg-chambers was measured. The result was clear : the egg-chambers of the twenty-two surviving females deprived of the neurosecretory cells measured 0·13–0·17 mm., whereas only two of the surviving twenty-eight controls had egg-chambers measuring 0·17 mm. and 0·18 mm., while of the remaining twenty-six controls, two flies oviposited, seventeen contained ripe eggs, and in seven flies the egg-chambers measured from 0·28 mm. to 1·25 mm., all egg-chambers containing normal yolk. No yolk was present in the egg-chambers of the flies lacking the neurosecretory cells (as a rule no yolk is deposited until the egg-chamber reaches a length of 0·25–0·30 mm.).

In twelve females, allatectomized at the same age and kept for seven days (25° C.), the length of the egg-chambers varied from 0·14 mm. to 0·23 mm., and no yolk was present in any of them (ref. 6, p. 357). Thus it is evident that the ovaries of the flies deprived of their neurosecretory cells only develop to the same, or nearly the same, stage as the ovaries of allatectomized flies. This result seems to indicate that the corpus allatum is activated from the neurosecretory cells, possibly through the corpus cardiacum.

As neurosecretory cells have also been found in the brain of dipterous larvæ, one might go a step further and suggest that the larval corpus allatum likewise is controlled by the neurosecretory cells of the brain. The investigation is being continued.

Ribose Nucleic Acid in the *Drosophila* Egg

Caspersson and Schultz[1,2] have claimed that the presence of an extra *Y*-chromosome in the female *Drosophila* is correlated with an abnormally high concentration of ribose nucleic acid or allied substances containing the pyrimidine ring in the cytoplasm of oocytes. Their graph, based on quantitative determinations of ultra-violet light absorption, indicates that *XXY* oocytes contain about 40 per cent more ribose nucleic acid than do *XX* oocytes. If confirmed, this claim would be evidence for the control exercised by heterochromatin over the synthesis of ribose nucleic acid: and since this substance seems to be closely associated with protein synthesis, the argument might be extended to include a specific connexion between heterochromatin and growth-rate determination.

Brachet[3] has recently described a simple microchemical method whereby ribose nucleic acid may be estimated quantitatively. The tissue under examination is hydrolysed and distilled in a current of steam. Furfural, the hydrolysis product of ribose sugar which appears in the distillate, is assayed colorimetrically, making use of the coloured compound which it forms with aniline and acetic acid.

Caspersson and Schultz's contention is not directly open to chemical proof since the collection of a homogeneous batch of *Drosophila* oocytes is impracticable. However, freshly laid eggs can be collected in quantity and these assayed for ribose content.

Such eggs were collected over hourly intervals from the matings *XX* × *XYY* and *XXY* × *XY*. They were dechorionated *en masse* and fixed in a mixture consisting of equal parts acetone and 10 per cent trichloro-acetic acid. After prolonged extraction in changes of fixative, the eggs were desiccated at 100° C., extracted with hot ether to remove neutral fat, hydrolysed and distilled. Furfural yields gave the following ribose nucleic acid assays:

	Weight of ether-extracted eggs (mgm.)	Yield of furfural (γ)		Estimated ribose nucleic acid (mgm. per gm.)
	5·9	11·3		6·48
	6·5	13·1		6·82
	6·6	13·5		6·94
Eggs from	6·6	11·6		6·00
XX females	7·0	13·3		6·45
			Average	6·54
	4·9	9·6		6·61
	6·5	11·7		6·11
	6·7	12·7		6·41
Eggs from	7·1	13·1		6·25
XXY females	8·7	19·0		7·39
			Average	6·55

From these figures it is evident that there is no significant difference in the ribose nucleic acid content of newly laid eggs deriving from *XX* and *XXY* parent flies. In keeping with this result it should be further mentioned that in other experiments, to be described in detail elsewhere, no difference either in developmental-rate or in oxygen consumption was found to exist between these two types of eggs.

Trypanosoma heptatretæ sp. n., a Blood Parasite of the Hagfish

HITHERTO the occurrence of a trypanosome in the blood of the hagfish *Heptatretus cirrhatus* (Bloch and Schneider, 1801) seems to have escaped notice. The type slide of *Trypanosoma heptatretæ* was prepared from the peripheral blood of a hagfish found stranded at Island Bay, Wellington. Seventeen (57 per cent) of thirty hagfish so far examined have been infected with this hæmoflagellate. One infection was so heavy that an average of three trypanosomes were present in each field when freshly drawn blood was studied under oil immersion (1·8 mm.) and a × 10 ocular.

Trypanosoma heptatretæ is of long, slender form, its body tapering to a point posteriorly. Its dimensions, from the measurement of one hundred specimens fixed with 4 per cent osmic acid vapour and stained with Giemsa's stain, are as follows:

	Average	Range
Length of free flagellum	21 μ	18–24 μ
Length of body	61 μ	56–65 μ
Total length	82 μ	75–86 μ
Width of body at nucleus	3·0 μ	2·8–3·1 μ
Width of undulating membrane	2·5 μ	2·3–2·7 μ
Diameter of karyosome	2·3 μ	2·0–2·5 μ

The length of the free flagellum averages 37 per cent (30–43 per cent) of that of the body. The nucleus lies 40 per cent (35–44 per cent) of the body-length from the root of the free flagellum, and occupies almost the entire width of the body. A parabasal body is situated 5 per cent (4 – 7 per cent) of the body-length from the posterior end, and the axoneme terminates at a blepharoplast immediately anterior to this structure.

T. heptatretæ also occurs in a very much scarcer stout form which has the free flagellum much shorter than that of the common form described above. The body is correspondingly lengthened and very markedly widened, but the overall length is not increased. In this stout form the nucleus is appreciably larger than in the slender form, and occupies a more central position. Measurements of the only three specimens encountered to date give the average length of the free flagellum as 12 μ and that of the body as 70 μ. The width of the body at the nucleus averages 6·3 μ, while the diameter of the nucleus itself is 4·6 μ and that of the karyosome 3·3 μ.

In both slender and stout forms the nucleus is of circular shape, and contains a large central karyosome. The space between karyosome and nuclear membrane appears as a clear, vacuolated ring in living specimens. With Giemsa's stain, used either after dry fixation with absolute alcohol or wet fixation with 4 per cent osmic acid vapour, the karyosome takes on a purplish-pink colour. The vacuolated ring between it and the nuclear membrane stains a light pink. Hæmatoxylin-stained preparations show the karyosome as a violet-stained body somewhat smaller in relation to the overall size of the nucleus as compared with Giemsa preparations.

The cytoplasm of the parasite stains a deep blue with Giemsa. It is dense, vacuolated and intensely granular, the granules staining purplish-black. As in *Trypanosoma granulosum* Laveran and Mesnil (1902), a parasite of *Anguilla vulgaris*, the granules are not apparent in hæmatoxylin preparations when the stain is properly extracted[1].

T. heptatretæ resembles *T. granulosum* in the granular nature of its cytoplasm, but is distinguished from this species by its circular nucleus and karyosome. These structures are very prominent in both stained and living specimens.

A more detailed account of *T. heptatretæ* is in course of preparation.

Relationship of Glioma to Encephalitis in the Domestic Fowl, and an Associated Parasitic Agent

THE occurrence of glioma in the brain of the fowl was reported by Belmonte[1] (one case) and by Jackson[2] (two cases). Later, Jungherr and Wolf[3] studied two cases and concluded that the tumours were astrocytomas. During the past twelve years I have had the opportunity of studying some fifty cases of the disease from material submitted by Prof. D. Coles of this Institute.

The histopathological observations led me to the following conclusions. (1) In the fowl, all gradations occur between lesions of chronic disseminated focal encephalitis and glioma, often in the same brain. (2) The histopathology of these chronic encephalitic foci is identical with that of the brain tissue at the margin of glioma—hypertrophy and hyperplasia of blood-vessels, perivascular infiltration (chiefly by lymphocytes, plasma cells and monocytes), and overgrowth and proliferation of astrocytes. (3) Avian glioma enlarges chiefly through progressive incorporation of these astrocytes into the tumour tissue—'growth by conversion' (of neighbouring cells to 'tumour cells'). (4) I cannot agree with Jungherr and Wolf (*loc. cit.*) that the multiplicity of the lesions in avian gliomatosis is due to cellular metastasis. I believe that each tumour arises as a focus of encephalitis.

These findings suggested that avian glioma is a response to some noxa which continues to spread in the brain tissue in advance of the tumour; not a 'purposeless' proliferation of cells.

A survey has been made to determine whether this disease might be associated with the presence of a visible biological agent, with the result that the following bodies have to be described briefly, with arbitrary designations for convenience of further communications.

A-bodies (Fig. 1): In sections these appear as oval or circular rosettes composed of an inconstant number of oval units (A^1-bodies), which radiate in orderly fashion around a central space, are readily stainable with nuclear dyes, and are Feulgen-positive. *A*-bodies may measure $10\,\mu$ in diameter (in smears, $18\,\mu$); the A^1-bodies about $2{\cdot}5\,\mu \times 1{\cdot}75\,\mu$. The latter can be seen in process of dispersion from the rosettes into the tissues. *A*-bodies have been seen in glioma and in chronic encephalitis, but are rare and quite unreliable of demonstration. But in two cases of more acute or purulent encephalitis they were present in large numbers.

Fig. 1 Fig. 2

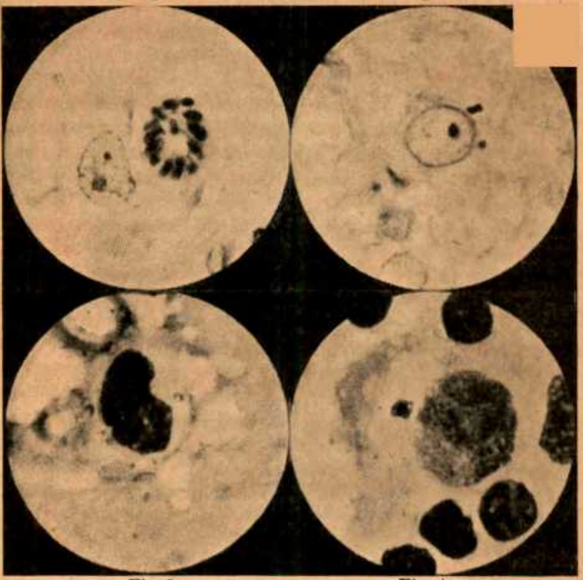

Fig. 3 Fig. 4

Fig. 1. *A*-BODY AT THE MARGIN OF A FOCUS OF CHRONIC ENCEPHALITIS. (ASTROCYTE NUCLEUS NEAR BY)

Fig. 2. *C*-BODIES (OVAL AND DOUBLE OVAL) IN THE CYTOPLASM OF A TUMOUR CELL. (GLIOMA)

Fig. 3. RING-SHAPED *C*-BODIES IN A MONOCYTE; OTHER FORMS ALSO VISIBLE. (SMEAR FROM GLIOMA)

Fig. 4. JUXTANUCLEAR, VACUOLATED *D*-BODY IN A HYPERTROPHIED ASTROCYTE. (BRAIN SMEAR—CHRONIC ENCEPHALITIS)

(ALL STAINED WITH GIEMSA. × 1200)

B-bodies: These represent the immediate precursors of *A*-bodies and there are all transitional stages. A somewhat refractile membrane encloses a central chromatic mass which later resolves into the *A*-rosette. They could be confused with a poorly fixed mitotic metaphase of a tumour cell. Their distribution is similar to that of *A*-bodies.

C-bodies: Much smaller elements, resembling small piroplasms or even *Rickettsiæ*. In both glioma and chronic encephalitic foci they can be demonstrated with considerable constancy if Giemsa-stained sections or smears are carefully searched. Oval, double-oval, piriform, bipolar and ring-forms are distinguishable (Figs. 2 and 3).

D-bodies (Fig. 4): Juxtanuclear, irregularly oval, moderately chromatic, in some respects reminiscent of Negri-bodies. They may be attached by a fine stalk to the nuclear membrane of a tumour cell or of an infiltrating cell. Typically they cause a shallow indentation in the nucleus. Unreliable of demonstration in fowl glioma.

It is my opinion that all the above bodies represent phases of a specific parasite. A pronounced tendency to the emergence of the *A*-body phase is associated with a purulent inflammatory reaction, whereas phases such as the *C*-bodies are associated with a more chronic reaction, the ultimate stage of which is a glioma.

Several additional bodies are strongly suspected of being still other phases of this pleomorphic parasite: *E*-bodies are intensely chromatic, torula-like, and can readily be confused with pyknotic nuclei or nuclear fragments. *H*-bodies are composed of chromatin and cytoplasm, the former with bipolar, tripolar or quadripolar distribution. They are likely to be dismissed as cells undergoing karyorrhexis. Possible filamentous phases are also being studied. Full descriptions, including details of the distribution in the tissues, will be published elsewhere.

I believe that glioma of the fowl will prove to be nothing but a proliferative response to a specific infectious agent.

These findings led me to approach Dr. R. A. Krynauw, head of the Neurosurgical Department of the Johannesburg Hospital, for collaboration in the task of ascertaining whether they have application also to gliomas of man. Results have been obtained which will be communicated in the near future.

Shrivelled Wheat Grain from Rust-Affected Crop as Seed

IN the Central Provinces and Berar and other regions in peninsular India, recurrent damage is caused to the wheat crop by black stem rust, *Puccinia graminis tritici*. In some years, as in 1946, the destruction of the crop is so great as to result in an acute shortage of seed. To investigate the possibility of utilizing the shrunken grain produced by the rust-affected crop, as seed, germination tests of, and experiments to observe the effect on yield of sowing, such grain were carried out.

Samples of shrivelled grain were obtained from different places and individually sorted into three grades according to grain size: medium, thin and very thin grains. Percentages of each grade in a sample and its 1,000-seed weight were ascertained before testing viability of the grain. Due to high weather temperature (about 115° F.) and for want of a refrigerator at this Station, germination tests were carried out in small earthen pots filled with sand and clay. The pots were partially buried in wet sand and kept in a cool room during the day, and removed to the open towards evening. The results of 120 samples thus tested are summarized in Table 1.

TABLE 1. SUMMARY OF THE RESULTS OF GERMINATION TESTS

(Figures represent the mean for the number of samples tested per lot.)

Lot No.	Number of samples tested	Percentage of grades*			1,000-grain weight in gm. of grades†			Germination percentage of grades		
		A	*B*	*C*	*A*	*B*	*C*	*A*	*B*	*C*
1	24	19	68	13	18·5	10·9	5·3	79	63	33
2	20	34	58	8	15·3	8·9	3·8	84	80	66
3	11	16	70	14	18·4	10·5	5·1	97	79	62
4	30	27	66	7	16·5	8·6	3·7	94	90	81
5	15	33	56	11	17·9	10·4	4·1	80	81	74
6	9	36	41	23	14·7	8·7	4·6	86	78	71
7	6	41	53	6	22·0	11·2	4·7	69	58	41
8	5	35	57	8	18·0	11·0	5·2	65	51	37
Average of 120 samples		30	59	11	17·7	10·0	4·6	82	73	58

* Grade *A* = medium grain; Grade *B* = thin grain; Grade *C* = very thin grain.

† 1,000-grain weight of normal wheat grain of the varieties tested varies from 36 to 40 gm.

TABLE 2. YIELD OF GRAIN (CALCULATED) PER ACRE (IN LB.)

Year	Variety	Shrivelled seed	Normal seed	Difference	Percentage loss
1944–45	*A*115	377	864	487	56·3
	*A*090	461	755	294	38·9
	*N.P.*52	472	588	116	19·6
		(*S.E.* 64·7 ;	*C.D.* 188·7)		
Average		437	736	299	38·3
		(*S.E.* 37·4 ;	*C.D.* 108·9)		
1945–46	*A*115	693	1205	512	42·5
	*N.P.*52	701*	1092	391	35·9
		(*S.E.* 94·7 ;	*C.D.* 285·3)		
Average		697	1149	452	39·2
		(*S.E.* 66·9 ;	*C.D.* 201·7)		

Critical difference (*C.D.*), at $P = 0{\cdot}05$. The differences are statistically significant.

* There was considerable damage to the plants by termites in these plots.

In order to observe how the crop grown from shrivelled grain would compare with that from normal seed, particularly in respect of yield, the two kinds of grain of three varieties, *A*090, *A*115 and *N.P.*52, were sown in plots, each 10 in. × 7½ in. in size and replicated six times. In the subsequent year, the trial was repeated but with the last two varieties. In both years the early growing period was dry and devoid of rain, resulting in seedling mortality which was approximately 20 per cent greater in plots sown with shrivelled grain. Plants from the normal seed were superior in growth, vigour and tillering. The yields obtained are shown in Table 2.

The results of germination tests indicate that shrivelled grains obtained from the rust-affected wheat crop are tolerably suitable as seed, particularly if the very thin grains are sorted out and rejected. From the point of view of yield, however, sowing such grain would lead to a loss of about 40 per cent as compared to that of the normal seed crop. As the seasons during which the trials were conducted were very adverse, it is probable that the loss would be less under favourable weather conditions. In the present circumstances in India, when good seed is not available, the possibility of importing it from outside is remote and the necessity of growing food crops is supreme, recourse could be taken to the use of shrivelled grain as seed.

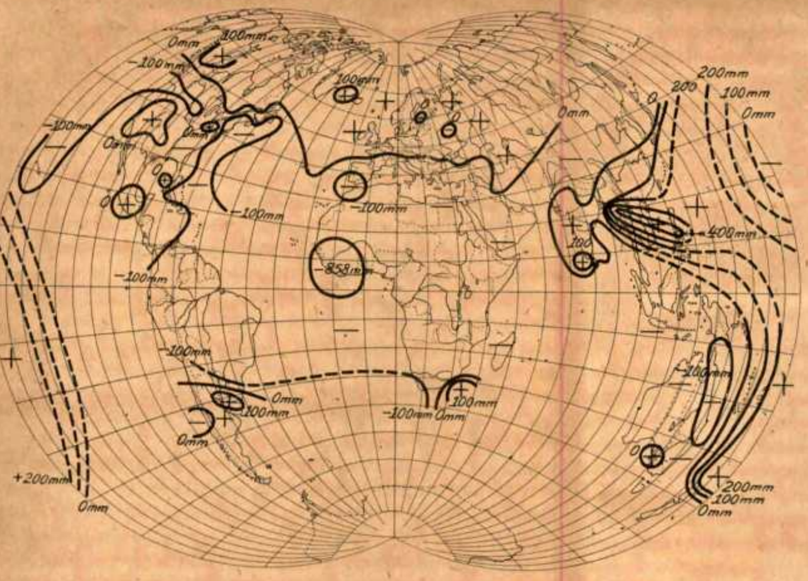
Recent Climatic Fluctuations

SOME researches have been carried out in order to elucidate recent climatic fluctuations. Maps have been constructed, showing for the whole earth: (1) the extension of severe winters and mild winters, cool summers and warm summers, cold years and warm years; and (2) the difference $T_{(1911-40)} - T_{(1881-1910)}$, $R_{(1911-40)} - R_{(1881-1910)}$ and $P_{(1911-40)} - P_{(1881-1910)}$ respectively; T, R and P are the normals of temperature, rainfall and pressure for the periods 1881–1910 and 1911–40, January, July and year.

Temperature-, rainfall- and pressure-curves have been worked out for 10-year means and overlapping 30-year normals respectively.

Certain regions seem to be connected in respect of climate, in that considerable positive or negative correlations can be found between the departures from the mean winter- and summer-temperature at the meteorological stations in these regions.



VARIATION OF RAINFALL, $R_{(1911-40)} - R_{(1881-1910)}$, mm.

Over great parts of the earth, especially in temperate and arctic zones, both winter- and summer-temperature seem to have been subject to an appreciable increase, while over other parts, especially in the tropical and subtropical zones, a decrease of temperature has taken place. Also an increase in rainfall is recorded over great parts of the temperate and arctic zones and over the monsoon regions of south-east Asia, while a decrease of rainfall is recorded over other tropical and subtropical regions, such as Africa, Australia, Brazil and the United States (see accompanying map).

A full account of this investigation will probably be published in the *Geografisk Tidsskrift*, Copenhagen, shortly.

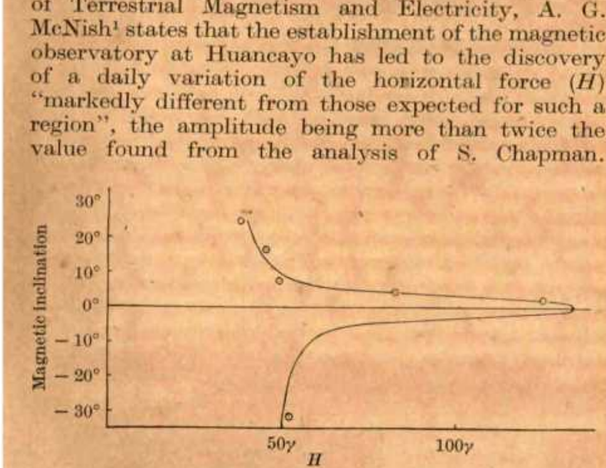
Daily Variation of the Horizontal Magnetic Force at the Magnetic Equator

IN a communication on the daily magnetic variation to the Edinburgh meeting, 1936, of the Association of Terrestrial Magnetism and Electricity, A. G. McNish[1] states that the establishment of the magnetic observatory at Huancayo has led to the discovery of a daily variation of the horizontal force (H) "markedly different from those expected for such a region", the amplitude being more than twice the value found from the analysis of S. Chapman. McNish has based his investigation on the assumption that the daily variation depends on magnetic co-ordinates, and points out that the daily variation of the declination varies considerably in a very narrow region at mag. lat. 0. The great daily variation of H at Huancayo is explained as an augmentation of the normal varying field originating from special circumstances. For Huancayo this augmentation, which is increasing when the distance of the magnetic equator from the geographic equator is increasing, is great.



VARIATION OF TOTAL RANGE OF THE VARIATION OF H WITH MAGNETIC INCLINATION

The present note gives the results from an examination based on the assumption that the daily variation depends on the distance of the place of observation from the magnetic equator (magnetic inclination = 0). The examination is made for H using the total range of the daily variation for all days (September) corresponding to mean sunspot number. The data are given in the table, namely, names of observatories, geographic co-ordinates, magnetic inclination and the total range of H.

TOTAL RANGE OF DAILY VARIATION OF H

Station	φ	λ	Mag. inclination	Total range
Alibag	18·6° N.	72·9° E.	24·4°	38·5 γ
Antipolo	14·6 ,,	121·2 ,,	16·2	45·5
Madras	13·1 ,,	80·2 ,,	7·6	49·5
Kodaikanal	10·2 ,,	77·5 ,,	4·3	82·5
Batavia	6·2 S.	106·8 ,,	− 31·6	52·3
Huancayo	12·0 ,,	284·7 ,,	2·3	125·0

In the accompanying diagram the variation of the total range of H with the magnetic inclination is given. The application of geomagnetic co-ordinates has been avoided in this case, for the magnetic field at the place—and not the magnetic field of the earth as a whole—is the deciding factor.

In accordance with the assumption, the curve has been drawn symmetrically to the line corresponding to the magnetic equator. The curve suggests the range is great only for a strip of land about 300 km. to both sides of the magnetic equator. This augmentation at the magnetic equator of the normal daily variation of H may therefore arise from a varying electric current flowing in a very narrow zone above the magnetic equator at a height of the same order as the E layer. The values of the total range for Huancayo and Kodaikanal are in agreement with the above explanation of the augmentation of the amplitude of the daily variation of H, but this is not the case as regards the values for Madras and Antipolo, for which observatories there seems to be no addition to the normal daily variation.

It should be added that E. V. Appleton[2] in a recent communication has shown the existence of a marked minimum in the F_2 layer critical frequency at mag. lat. 0. Possibly a connexion exists between this phenomenon and the augmentation of the variation of H at the magnetic equator.

However, more observations of the daily variation of H from stations near the magnetic equator are needed before a complete representation of the variation with the magnetic inclination can be given.

Further, it may be desirable to examine the special electric conditions in the atmosphere over the magnetic equator by means of radio investigations.

Citizenship and Current Affairs in Army Education

THE following observations may perhaps serve to allay certain misgivings expressed in your thoughtful and constructive leading article in *Nature* of February 21, dealing with Army education, at the "undue emphasis" placed by the Army Council on citizenship and current affairs in the recently announced Army Education Scheme (Interim Period).

In any system of education it is inevitable that, for purposes of analysis and administrative convenience, there should be division into categories, and into subjects. Thus, in the new Army Education Scheme, there are the broad divisions of general education and individual education, and the former is itself divided into subjects of primary instruction, with the addition of citizenship and current affairs. Despite these necessary divisions it is not intended that any category or subject shall be dealt with in isolation, but rather that all subjects shall combine to foster the development of the responsible and well-informed soldier-citizen. Training in citizenship, therefore, will be the student's concern not only in periods set apart for that purpose but also in those devoted to the ordinary subjects of the curriculum; conversely, the study of public affairs cannot proceed without, and indeed must to some extent be based on, attention to historical and geographical considerations, to mastery of the basic skills of general education, and to the part which science plays in the modern world.

The distinction is rather one of emphasis. The young soldier joining the Army is given a short initial course in citizenship and current affairs, provided he is not in more urgent need of special instruction in elementary reading and writing. This first course is part of his introduction to the Army. It seeks to explain the need for service and to awaken in him a realization of the responsibilities as well as the privileges of citizenship. Later, the emphasis swings in the direction of consolidating his general education in primary subjects, a process to which two thirds of the time available for compulsory education is devoted. After the first twelve months of service a further change of balance takes place, and for the next two years, for those who are staying on in the Army beyond the period of national service, citizenship and current affairs share together an equal place with instruction in primary subjects. Finally, after the third year of service, citizenship and current affairs remain the only compulsory subjects in the curriculum, though facilities in working hours will continue to be made available for the pursuit of voluntary studies (a position identical with that occupied from the start of their service by those exempt on educational grounds from the provisions of general education).

It will be seen from the above that training in citizenship is in a sense the hard core of the Scheme, forming thereby the most important single factor making for a balanced and integrated curriculum. Certain cogent considerations may be held to justify this choice. First, it is a theme particularly relevant to adult students, for the man, unlike the boy, can quickly be made conscious that he has a stake in the community; matters which in the schoolroom can only be considered in the abstract take on with the approach of adulthood a reality and a seriousness which only maturity and experience can give. Secondly, the war-time experiment of current affairs discussions together with systematic study of the "British Way and Purpose" gave, despite many imperfections, convincing proof that the product of such periods was valuable in the way of improved officer–man relationships as well as increased social awareness.

It is true that discussions of this nature cannot always be divorced from political considerations, since politics is the art or science of living in society. But the discussions must be conducted with good temper and objectivity, and party political bias is not allowed to dominate them. It is true, too, that present educational standards among the majority of young men and young women entering the Army are such as to lay emphasis on the need for careful and accurate presentation of information as a necessary preliminary to any exchange of views. This is not lost sight of, and it may be pertinent to mention in this connexion the valuable contribution in this field made by the B.B.C. in its current affairs broadcasts for the Forces—factual commentaries valuable either as the raw material of discussion or as briefing matter for the instructor.

There are two further, and perhaps less obvious, reasons why current affairs discussions may be considered to play a particularly valuable part in the Army Education Scheme. First, the regimental officer has a special responsibility in acting as chairman at such discussions. This cannot but have a potent effect in driving home his personal responsibility for the educational progress of his men; he has a definite part to play and is therefore in less danger of considering education as something apart from the normal life of the unit, something to be left to the specialist instructor. The basis of the Army is the unit, and the best laid educational plans can only come to full fruition as an expression of unit life and experience. Finally, the current affairs discussion group is not based upon an educational grouping; that is to say, it is not composed of individuals of approximately equal educational attainment but is a cross-section representative of the unit as a whole, since it is composed upon a platoon basis. There are thus brought together individuals differing widely in interest, occupation and intellect but united by the common bond of fellowship within their small community. That throughout the Army men and women should be meeting regularly in small groups, under the chairmanship of their own officers, to discuss together some current topic of common interest is surely expressive of our democratic way of living and is powerful for good in its opportunities for the development of those qualities of tolerance, fair play and understanding on which as a nation we set such store.

ALKALINE PHOSPHATASE IN TASTE BUDS AND NASAL MUCOSA

By DR. GEOFFREY H. BOURNE
London Hospital Medical College

THE application of Gomori's (1939) technique for the demonstration of alkaline phospho-monoesterase to various organs and tissues of the body[1,2,3] showed the enzyme to be located in many hitherto unsuspected sites. In view of its association with the absorptive part of the alimentary tract, and since the process of tasting and smelling appear to involve an absorptive process, it was considered desirable to test for phosphatase in taste buds and olfactory mucosa. Pieces of tongue of bat (*Nyctalus noctula*), mouse, rabbit, monkey (*Cercopithecus griseus*) and human being, and pieces of mouse, rabbit and human olfactory and nasal (respiratory) epithelium were therefore treated by Gomori's technique.

In the bat's tongue, alkaline phosphatase was found in high concentration in patches of basal cells in the stratified epithelium. The only other sites where it was present were the taste buds themselves (Fig. 1), the gustatory pores, the gustatory hairs and, in some places, in the superficial epithelial cells surrounding the gustatory pore. So far as could be seen, all the cells in the taste buds gave a phosphatase reaction of equal intensity.

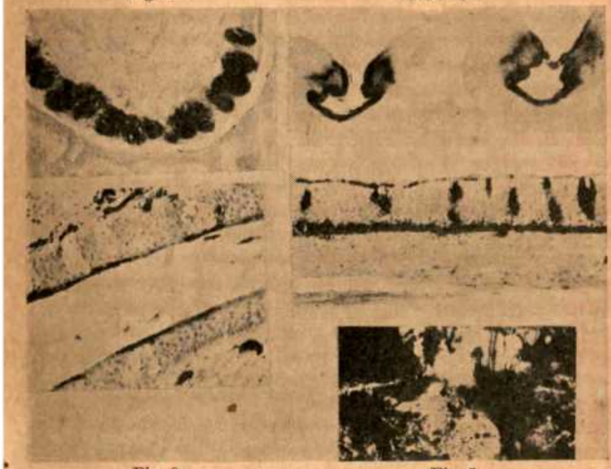

Fig. 1 Figs. 2, 4

Fig. 3 Fig. 5

LOCALIZATION OF ALKALINE PHOSPHATASE IN TASTE BUDS, ETC.: (1) TONGUE OF BAT (*Nyctalus noctula*); (2) BETWEEN PAPILLÆ, FOLIATA OF RABBIT'S TONGUE; (3) EPITHELIUM OVERLYING TASTE BUDS IN HUMAN TONGUE; PHOSPHATASE-POSITIVE CAPILLARIES CAN ALSO BE SEEN UNDER THE EPITHELIUM; (4) INNERMOST LAYERS OF BASAL CELLS IN RABBIT MUCOSA; PHOSPHATASE-POSITIVE STRANDS CAN BE SEEN PASSING THROUGH THE MEMBRANE TO THE SURFACE. (5) ALKALINE PHOSPHATASE IN SMEAR OF HUMAN NASAL MUCUS. SOME PHOSPHATASE-POSITIVE LEUCOCYTES CAN ALSO BE SEEN. ALL REPRODUCTIONS × 75

Serial sections of mouse's tongue were examined but no typical taste buds were seen. Numerous filiform papillæ were present, most of which contained a core which gave a strongly positive phosphatase reaction.

In the papilla foliata of the rabbit's tongue, the epithelium of the folds between the papillæ, in which the taste buds are situated, gave a strong positive reaction localized in the superficial layers of the epithelium overlaying the taste buds (Fig. 2). A reaction also occurred in a layer of cells deeper in the epithelium (shown in figure) in the upper part of the inter-papillary fold.

The monkey's tongue showed (like the bat) alkaline phosphatase concentrated in the taste buds. It was present also in the epithelium on the opposite side of the fold carrying the taste buds. In the bud itself, the central cells gave a stronger phosphatase reaction than the peripheral cells. The gustatory hairs were phosphatase-positive, and in some taste buds the distal ends of the cells gave a strong phosphatase reaction whereas the proximal parts of the cells gave a much less intense reaction.

Human taste buds did not appear to contain phosphatase (Fig. 3). This result might have been due to the fact that there had been some post-mortem degeneration of the cells (the specimen was 12 hours old). It was found, however, that there was no difference in the phosphatase reactions in the tongues of fresh or 12-hours dead rabbits, so presumably the absence of reaction in the human taste buds was not due to post-mortem changes.

The distribution of alkaline phosphatase in the human tongue resembled that of the rabbit, in that the reaction was concentrated in the superficial layers of the epithelium overlaying the taste buds. In those parts where the buds were separated from each other by a short space, it could be seen that the phosphatase was localized only in the epithelium surrounding the taste buds. In regions where the buds were close together, these areas linked up to form a continuous layer. The gustatory hairs appeared to give a positive reaction, and the walls of the gustatory pores gave a very dense reaction.

The distribution of phosphatase in the gustatory apparatus therefore appears to be of two types. Bat and monkey belong to one type, and human and rabbit to the other.

Olfactory mucosa of the rat gave a positive reaction for phosphatase, but the superficial cells of the epithelium gave only a slight reaction. The reaction was concentrated almost entirely in the lower layers of the basal cells. Beneath this basal layer were sparsely arranged phosphatase-positive cells, apparently ganglion cells, which gave off fine, greatly elongated, phosphatase-positive processes. Respiratory mucosa in the nose gave little or no reaction.

The olfactory mucosa of the rabbit was similar. As in the rat, the lower basal cells of the epithelium were strongly positive; but in addition, what appeared to be groups of three or four cells which were in contact with the basal layer extended through to the surface of the mucosa and gave as strong a phosphatase reaction as the basal cells. Parts of these strands can be seen in Fig. 4. There was also a thin line of phosphatase over the distal surface of some of the cells. Bundles of olfactory nerve fibres also gave a moderate positive reaction. (The strand at the bottom of Fig. 4 is such a bundle.) In some parts of the epithelium, these phosphatase strands appeared to be composed of one cell; but in others the strand seemed made up of three or four cells. It has not been found possible so far to differentiate these areas histologically from others in the nasal mucosa; they are not frequent enough to be the olfactory cells and it seems unlikely they represent ducts of Bowman's glands. Perhaps they represent a biochemical rather than an anatomical entity.

In the human olfactory mucosa the basal cells were almost completely phosphatase-negative, but the distal columnar cells (both olfactory and sustentacular) were positive; olfactory hairs were also positive, but no more so than the bodies of the cells. A number of cells immediately beneath the basal cells and which appeared to be of a ganglionic nature gave off elongated processes with a phosphatase-positive reaction. Bundles of olfactory nerve fibres were negative.

In the non-olfactory epithelium, goblet cells were negative; other cells gave a slight reaction. Running along the outside of the free edge of the cells was a thin positive line, which was probably a line of mucus-containing phosphatase. Smears of human nasal mucus fixed in alcohol and incubated with the usual phosphatase substrate mixture gave positive results (Fig. 5).

Bowman's glands beneath the nasal mucosa showed both phosphatase-positive and phosphatase-negative acini. Most of the latter appeared to belong to the mucous category and the former to be of a serous nature.

The significance of these findings is not obvious at the moment. They show, however, that the membranes of the nose as well as those of the mouth are continuously bathed in alkaline phosphatase-containing fluids (saliva has for some time been known to contain the enzyme), and all substances requiring to be tasted or smelled must, therefore, pass through these fluids. Those being tasted must penetrate a further intra- or extra-cellular phosphatase barrier, either in the taste buds themselves or before the taste buds are reached. Such an arrangement may perhaps help to explain the mechanism of tasting of sugar, but it seems scarcely likely to explain why greatly unrelated chemical substances such as saccharine (*o*-benzoic sulphimide), *p*-phenetylurea, cinnamic aldehyde, certain aliphatic chlorides (for example, chloroform) and salts of lead and beryllium also taste sweet.

The piece of human tongue used was taken from the posterior position, a region which, like the tip, is sensitive to all the primary taste sensations; and the arrangement of the phosphatase was similar in all the taste buds examined, so it seems possible that phosphatase is not necessarily restricted to the buds concerned with the detection of any one of the primary tastes.

In view of the supposed similarity between the mechanisms of taste and smell, it is not surprising to find that substances to be smelled appear also to require to be passed through a phosphatase barrier; but the remarkable arrangement of phosphatase in the rabbit's nasal mucosa needs some explanation.

In addition to the chance of some connexion with the mechanism of taste and smell, there exists the possibility that the presence of phosphatase in the naso-buccal fluids may be concerned with some anti-infective mechanism. Thus it is of interest that it is the apparently serous alveoli in the Bowman's glands which contain phosphatase, and that in an acute infection such as a cold there is a great increase in serous secretion in the nose.

Full details of this work will be published elsewhere in due course. I am indebted to Dr. J. W. Sandells for the supply of human material and to Mr. J. King of the Bernhard Baron Institute, London Hospital, for the photomicrographs.

DIETETIC HEPATIC LESIONS AND PROTEIN DEFICIENCY

By Dr. M. V. RADHAKRISHNA RAO

At the Medical Unit, University College Hospital Medical School, London

SEVERAL workers[1-14] have studied the hepatic lesions resulting from feeding deficient diets to experimental animals, and often produced fibrosis in the liver similar to that of human 'cirrhosis'. As a result of the recent researches a new orientation has been given to the etiology and treatment of liver diseases in general and 'cirrhosis of the liver' in particular. Himsworth, who has largely contributed to an understanding of this subject, in a recent monograph[17] has summarized the available evidence, both clinical and experimental, regarding nutritional factors in hepatic diseases.

Himsworth and Glynn[15,16] have distinguished two kinds of experimental dietetic injury in the liver, both of which resulted in hepatic fibrosis. Deficiency of protein (cystine) in the diet produced an acute massive hepatic necrosis, the survivors of which developed post-necrotic scarring and nodular hyperplasia. On the other hand, absence or deficiency of lipotropic factors in the diet, such as choline or methionine, resulted in fatty infiltration of the liver, which insidiously developed into diffuse hepatic fibrosis. By carefully devising the experimental diets, these workers were able to produce these two distinct lesions independently of each other. While there is general agreement that heavy prolonged fatty infiltration of the liver, however produced, leads to a diffuse hepatic fibrosis ('portal' or fatty cirrhosis), there is considerable disagreement regarding the production of acute massive necrosis and its sequelæ. Certain workers produce it consistently, others occasionally, yet others not at all. I personally have never been able to produce it in my laboratory in Bombay, although following closely the published directions. Since coming to England, however, I have seen it produced readily, and I have now amply satisfied myself of its occurrence, its dependence upon a low protein diet, and that it is, in fact, a true massive necrosis of the liver. It may, therefore, be of interest to record my experience in the hope of throwing some light upon the discrepancies between the results from different laboratories.

The incidence of 'cirrhosis of the liver' is high in certain parts of India, and it has been pointed out that "dietetic deficiencies appear to be the important factors in the causation" of the disease[18]. In view of its practical importance, an experimental investigation was undertaken under the auspices of the Indian Research Fund Association to study the role of nutritional factors in the production of hepatic cirrhosis. This investigation, which was commenced three years ago and is still in progress in the Department of Nutrition and Experimental Pathology, Haffkine Institute, Bombay, was designed to study the effect of continued feeding of diets containing varying levels of protein (5–18 per cent), and deficient in vitamins of the B$_2$ complex on the histological and biochemical changes in the liver of rats. Studies were also made on the effect of feeding low protein – high carbohydrate and low protein – high fat diets, and the effect of supplementing these diets with choline and methionine. Purified casein was used as the main source of protein, but in some experiments this was completely replaced by yeast protein. Either melted butter-fat, hydrogenated groundnut oil or groundnut oil formed the fat ration in the synthetic diets.

An analysis of the material collected during the last three years showed two prominent features: first, absence of acute massive necrosis of the liver or its sequelæ, in animals fed on low protein diets (including those which received yeast as the main source of protein); and secondly, varying degrees of fatty infiltration of the liver insidiously developing into diffuse hepatic fibrosis with accumulation of 'ceroid'. Full details of this work will be published shortly.

While no explanation is forthcoming regarding the constancy of producing massive necrosis of the liver by dietary means, several factors, such as differences in the susceptibility of different strains of experimental rats, nature of yeast used as the source of protein, climatic factors (hæmorrhagic necrotic lesions, even in England, appear to be more easily produced in winter than in summer), differences in the intestinal flora of experimental animals, etc., have been suggested to explain the difficulties in the production of the lesion. It was further suggested that the presence or absence of tocopherol (vitamin E) in the basal diets may have an important bearing in preventing or inducing necrosis of the hepatic parenchyma[19,20]. The possibility of a superadded infection producing the periportal hæmorrhages and acute massive necrosis of the hepatic parenchyma requires further investigation.

But whatever the ultimate explanation of the causation of massive hepatic necrosis, two things are certain now. First, a lesion in every way similar to human massive necrosis of the liver has at last been produced in experimental animals; secondly, a state of protein deficiency is an essential, if not the only, factor in the development of the lesion. Having these certainties, and considering the great practical implications of this work to medicine, it is of urgent importance to resolve the discrepancies between the results obtained in different laboratories. The first step to this end is for the work to be repeated in all the laboratories concerned using, not merely foodstuffs that are reputed to be similar, but identical foodstuffs directly drawn from the same stocks as are in use in those laboratories where positive results are consistently obtained.

MEASUREMENT OF 'ENVIRONMENTAL RESISTANCE' IN THE AUSTRALIAN PLAGUE GRASSHOPPER

By Dr. H. G. ANDREWARTHA
AND
L. C. BIRCH
Waite Agricultural Research Institute, Adelaide

LABORATORY and field experiments have shown that the Australian plague grasshopper, *Austroicetes cruciata* Sauss, is well adapted to live in the particular climatic zone where it is found[1]. An obligate diapause in the egg-stage ensures that the grasshopper produces only one generation each year[2]. Eggs are laid during November and December (late spring and early summer), but never hatch before the following August or September. Thus the active stages are present during two or three months in the spring when the physical environment is least severe. For the remaining nine months, comprising the hot dry summer and cool wet winter, the insects are in the soil in the egg stage, which is well adapted to resist desiccation during the summer and high humidity during the winter.

Nevertheless, variability of the weather in the grasshopper belt is such that all stages of the grasshopper are exposed to the risk of occasional heavy mortality from physical causes. It has been possible to assess the chances of heavy mortality due to several components of the physical environment. The calculations are no more than first approximations, since they are based on arbitrarily selected parameters of the weather and not on the whole distribution of records of rainfall, temperature and humidity for the fifty years used in the calculations. But we give them because they may interest ecologists who are concerned with the quantitative study of animal populations. The data on which the calculations are based are given in full in the publications cited.

During heat waves, the soil in which the eggs are laid may reach a temperature of 60° C., and at the same time the relative humidity of the soil atmosphere may be as low as 10–20 per cent. Laboratory experiments and field observations have shown that the probability of high mortality due to the direct effect of such high temperature in the summer is quite small[3]. On the other hand, the chances of death from desiccation is much greater. The severity of the summer dryness makes this the most critical period for the egg, despite the fact that the egg is more resistant to desiccation during the summer than at any other stage of its development[4]. The mortality of the eggs in the summer is related to the longest dry spell within the months November to April. A 'dry spell' is defined as the number of days during which the soil moisture is below the 'wilting point'. In the very dry summer of 1940, there was 90 per cent mortality of eggs in the driest part of the grasshopper belt. There the longest period without rain lasted 80 days, and during this period the total evaporation was 40·6 in. This severity of dryness had been reached or exceeded from one to seven times in the last fifty years, depending on the district. Hence the probability that the mortality of eggs in the summer will exceed 90 per cent is of the order 2–14 per cent[3].

In the winter the eggs are least resistant to desiccation, but the chance of dryness or excessive wetness causing high mortality is quite remote. In the early spring, however, there is a critical period at the time the eggs are hatching. Eggs may hatch in soil well below the 'wilting point', but under these conditions the nymphs are unable to escape from the pod because of the caked lid entrapping them. By methods analogous to those described above, it was estimated that 'high' mortality from this cause might occur about twelve times in a thousand years[3].

Information on the influence of dryness in the spring on the mortality of nymphs and adults was obtained from a detailed study of the weather during 1940. In September of that year the grasshoppers hatched in plague numbers, but by October it was virtually impossible to find a grasshopper anywhere. It was estimated that droughts, as severe as that in 1940 had occurred from three to five times during the past fifty years, depending on the district[5].

The calculations were made for several districts in the grasshopper belt. As an example, the figures for the district of Hammond are given in the accompanying table.

Stage	Cause of 'high' mortality	Probability of 'high' mortality
Egg in diapause	Desiccation during summer and autumn	0·10
Egg developing	Weather during winter and spring	nil
Nymphs in soil and about to hatch	Drought during August–September	0·01
Nymphs and adults (active stages)	Drought during spring and early summer	0·10
	Excessive humidity during spring	Not measured
Any stage	Any of above causes	0·21

Since the probability of a high mortality-rate occurring in any one year from any of the causes which have been measured is 0·21, the probability of this not occurring is 0·79. By expanding the binomial $(0{\cdot}21 + 0{\cdot}79)^n$, we can calculate the probability that any group of n years will contain 0, 1, 2 . . . n years in which high mortality will occur. For example, the probability that a sample of ten years will contain no 'high-mortality' year is 0·09; the corresponding figure for a sample of five years is 0·31. Within the limits of the parameters chosen, these figures give a quantitative measure of the favourableness of the environment for *A. cruciata*.

The table does not include any figures for parasitism or predation. Eggs are parasitized by a Scelionid wasp[6]; in the years studied, this did not exceed 1–2 per cent. Small numbers of eggs are also destroyed by a Bombyliid of the genus *Cyrtomorpha* and an unidentified Dermestid beetle. But the most important predators are birds, which feed on nymphs and adults. In years when grasshoppers are abundant, the population seems so vast in relation to the bird population that the percentage reduction in numbers of grasshoppers through predation is probably small. Observations in drought years suggest that predators may be important in causing heavy mortality in the isolated concentrations of grasshoppers that survive the drought. Food for the predators is then scarce and they are forced to seek out the remaining local situations where any grasshoppers remain. To this extent predation operates in the reverse direction to which parasitism would be expected to operate on a declining population[5].

The remarkable adaptation of the grasshopper to its semi-arid climatic zone enables it to build up a population over a number of years until drought causes a crash in numbers, both through its direct effect of desiccation on the grasshopper and indirectly through its effect on the food supply. The fact that grasshoppers and plants can continue to exist together in this belt must depend largely on the respite the vegetation is given in the ten months of the year in which the grasshopper is in the egg stage. So far as the grasshopper is concerned, the complete annihilation of nymphs in drought years is prevented by the existence of scattered niches, be they ever so small, where some food remains.

RESEARCH IN INDUSTRY

WORKING PARTY REPORTS

UNLIKE the majority of the reports from other 'working parties' of the Board of Trade, that for the cutlery industry (H.M. Stationery Office, London, 1947, pp. 38. 1*s*. net) makes no specific recommendations for the organisation of research, although it suggests that much research could be co-ordinated with research in other industries, and that the co-operation of such organisations as the Production Efficiency Service of the Board of Trade should be very valuable. Its principal recommendation is the constitution of a tripartite Cutlery Board, all the members of which, including the chairman, would be appointed by the Board of Trade, one third of them from nominees of the employers' association, one third from nominees of the trade unions, and one third from independent persons outside the industry. This Board would presumably call on the assistance of the Department of Scientific and Industrial Research, as the industry is not wealthy and will need financial assistance for effective research. Suggestions for certain specific lines of research are appended to the report.

The 'working party' dealing with rubber-proofed clothing, in its report (H.M. Stationery Office, London, 1947, pp. 40. 1*s*. net), likewise makes no recommendation for the establishment of a fresh research organisation, although exercised both by the need for research in such neglected fields as those of machinery and ventilation, and by the need for rubber-proofed clothing manufacturers to show keener interest in the results of research already carried out, such as that on lighting, productive efficiency, the science of management, industrial psychology, and the development of new fibres. In advance of the setting up of any development council, trade organisations could do much by operating in conjunction with existing institutions, where relevant, such as the British Cotton Industry Research Association and the India Rubber Research Institute, to bring about a new attitude.

The 'working party' also suggests that the industry should consider making an early approach to the Department of Scientific and Industrial Research for advice and practical guidance in this field. An increasingly active interest in textile research and development, particularly new finishing processes, and also in the development of plastics, is a specific recommendation for action by the industry which indicates its past neglect and restricted outlook—defects possibly only to be corrected as the industry becomes conscious that it is a section or part of a larger industry.

The 'working party' for hand-blown domestic glassware, in its report (H.M. Stationery Office, London, 1947, pp. 143. 3*s*. net), devotes rather more attention to technical research and recommends consideration by the glass industry of the expansion of technical research for the whole industry by setting up a glass research association, which should have initially an annual income, including the contribution from the Department of Scientific and Industrial Research, of at least £25,000. The 'working party' recommends that the University of Sheffield should be asked to consider the possibility of permitting this research association to be established initially in the existing buildings of its Department of Glass Technology, and also of leasing some of the land belonging to the University, behind and adjacent to the present building, for the erection of new laboratories, etc., as the work of the Association develops. The research association should be provided with a staff separate from that of the Department of Glass Technology, although for a time the position of director of research might usefully be held by the head of the Department. The annual income of the research association should be increased within five years at most to about £50,000 to enable a machinery research and development section to be created.

From this recommendation there is one dissentient. While agreeing wholeheartedly with the view that greater facilities for co-operative research into glass and glass manufacture are urgently desirable, Prof. H. Moore does not entirely agree that the formation of a glass research association is essential. In his view, the existing Department of Glass Technology at the University of Sheffield, if properly staffed and financed, could make adequate provision for these additional research needs. It is pointed out in the report that the organisation and functions of this Department are very similar to those of a research association, differing chiefly in its constitution as a department of a university and in the inclusion of educational work. The value of this educational work is emphasized in the report, which notes that this Department is the only place in Britain where technical training for the glass industry is available; the close contact maintained with the industry through the other activities of the Department greatly enhance the value of that work, while the long-term postgraduate investigations proceeding in the Department ensure that its activities are not entirely engrossed in the solution of day-to-day problems or in short-term investigations.

The report itself scarcely supplies the data which would enable an outsider to judge between the merits of Prof. Moore's view and that of the majority of his colleagues; but economy considerations, particularly of man-power, might well provide a decisive reason for exploring the possibilities of his view first. Beyond this, however, in spite of the small size of the units in the hand-blown glass industry, development and extension of technical research in the individual factories is highly desirable, and one reason for welcoming the formation of a new trade association comprising all firms in this section of the industry is that it would enable more research to be done on co-operative lines in the factories themselves on their own special problems. In addition to emphasis placed on the early initiation of research on the development of new types of machinery and equipment for the industry, the establishment of a design centre for the industry as a whole, and all possible encouragement and assistance to the scheme for setting up in Edinburgh a department for advanced training and research in design for the glass industry, are other important recommendations; while in common with many of the other 'working parties', that for the domestic glassware urges the industry to refer to the Urwick Report on Education for Management, and make contact with the British Institute of Management, so that it can endeavour to draw its recruits for managerial positions from a wider field. Greater use of glass technologists who have graduated from the Department of Glass Technology at Sheffield, and further support both of the educational side of that Department and of the Society of Glass Technology, are specific recommendations.

FIFTH BRITISH EMPIRE FORESTRY CONFERENCE

GREAT BRITAIN, 1947

THE Fifth British Empire Forestry Conference met in London on Monday, June 16, 1947, and a Summary Report and Results and Reports of Committees have now been published (London: H.M. Stationery Office, 1947. Pp. 56. 1*s*. net). The opening meeting of the Conference was attended by Mr. Tom Williams, Minister of Agriculture and Fisheries, and Mr. Joseph Westwood, Secretary of State for Scotland. Lord Robinson was elected chairman, and Mr. D. Roy Cameron (Canada), Mr. A. P. F. Hamilton (India), and Dr. F. Y. Henderson (director, Forest Products Research Laboratory, England) were elected vice-chairmen. Seventy-one delegates, thirty-eight associate delegates, one honorary delegate and three guests—Mr. G. M. Hunt, director of the Forest Products Laboratory, Madison, United States, and Messrs. S. B. Show and J. D. B. Harrison, of the Forestry Branch of the Food and Agriculture Organisation of the United Nations—attended the Conference.

The proceedings were somewhat similar to previous conferences. A comprehensive agenda prepared by a standing committee on Empire forestry, after consultation with the various Empire forest authorities, was dealt with at sessions held in London and Oxford. Visits were also paid to the Forest Products Laboratory at Princes Risborough and to saw mills and timber yards in the neighbourhood of London. Part of the work consisted of visits to some of the extensive conifer forests under the management of the Forestry Commission, and some private woods in Northamptonshire, Dumfriesshire, and Darnaway, in the County of Moray. The Forestry Commission areas visited were East Anglia, Northumberland, Cumberland, Roxburghshire and the Black Isle in Ross-shire and Cromarty, and the Culbin Sands.

Thirty-six forest authorities presented statements on Empire forests during the War. These statements have been drawn up with the view of giving as much accurate information as is at present available on the subject of the total area of forests; total volume of standing timber and increment; output of home-grown woods and of imports and exports for pre-war years, and each of the war years; and the effect of the war-time exploitation on forest capital and the future increment.

Owing to the very heavy war fellings made in countries both within the British Empire and outside, it is probable that accurate figures will not be available for some time to come. Moreover, in many of the forests under the Colonial Office, which are tropical forests containing numbers of different species of tree, very little is yet known about the actual volume present of commercially utilizable timber, and many of them have had to bear heavy war fellings in the accessible parts.

A most interesting paper was prepared by Mr. Lyle F. Watt, chief of the Forest Service, United States Department of Agriculture, entitled "The Forest Situation in the United States". Reports were made on the steps taken to carry out the resolutions of the 1935 Conference. These resolutions were nine in number, and for the information available the summary report should be consulted.

Technical committees were appointed as follows: (*a*) Land Use; (*b*) Forest Management, Sylviculture and Protection; (*c*) Forest Products Research; (*d*) Survey and Resources; (*e*) Education; (*f*) Timber Supply.

Various resolutions were drawn up by these different committees and submitted to the main Conference at its final meeting on July 19. The next Conference will take place in 1952, either in India or Canada.

MAGNETIC FIELD OF MASSIVE ROTATING BODIES

IT may be permissible to add a footnote to the much-discussed article by Blackett[1], in which he examines the proportionality which seems to exist between the magnetic moment and angular momentum of massive rotating bodies such as the earth, sun and stars. He suggested that this simple result must have some profound physical significance, but that it seemed very probable that a satisfactory explanation would not be found except within the structure of a unified field theory. The purpose of this note is to direct attention to the claim of Prof. J. Mariani, of the Princeton Institute of Advanced Study, to have provided such an explanation and such a unified field theory. Mariani's more accessible publications appeared in *C.R. Acad. Sci. Paris*, **206**, 1247 (1938); **211**, 430 (1940); **218**, 447 and 585 (1944); and "Electromagnétisme et relativité" (Cahiers de Physique Théorique, Paris, 1945), Part 1. However, the present summary has been prepared from his latest work, "Théorie des champs macroscopiques"[2], and a communication submitted to *Nature* for publication among "Letters to the Editors".

Mariani's latest treatment starts from philosophic considerations, akin to those of Kant, concerning the impossibility of knowing 'the thing in itself'. From the point of view of the average physicist, this is unfortunate. Even if he has the patience to read it, he may merely draw the depressing conclusion that no objective scientific measurement can exist. The next section of the work is something like a generalized theory of relativity, but with many coefficients that are quite indeterminate. Then suddenly, by means of a principle of identification, the treatment becomes much more definite. All the equations, except one, reduce to something like the ordinary gravitational theory of relativity. The one exception is the distinctive point of the theory, and its significance seems to be that a gravitational field must necessarily be accompanied by an electrical field.

The application of the theory to massive rotating bodies then proceeds very much on the lines of Sutherland, whose work is discussed in Blackett's article. The earth is supposed to have a positive volume charge compensated by a negative surface charge. This gives the desired proportionality between magnetic moment and angular momentum. The constant of proportionality is worked out for the earth, the sun, and the milky way, and shown to be of the right order of magnitude. It is also shown that for a copper sphere of radius 10 cm. making 200 revolutions per second, the magnetic field is too small to be observed. This agrees with the experiment of Swann and Longacre, also discussed by Blackett.

Those who are interested in the matter will wish to examine Mariani's arguments for themselves; they will probably find the four short papers in *Comptes Rendus* easier to understand than the fuller and more philosophic version.

H. T. H. PIAGGIO

RECENT SOCIOLOGICAL PERIODICALS

APART from the specialized field of economics, Britain has, until recently, suffered from a lack of journals devoted to the social sciences. The deficiency is now being made up by a variety of periodicals. *Pilot Papers*, as their subtitle of "Social Essays and Documents" suggests, usually take a wide sweep; but the number for June 1947 is devoted largely to American sociology. It contains a detailed review, by Dr. E. A. Shils, of recent American contributions to urban sociology, class stratification and race, family and small group problems, for which all students must be profoundly grateful. There is also an admirable study of the American child by Mr. Gorer, stressing the dictatorship of such factors as the 'scientific feeding schedule' and the fear of being thought a 'sissy'.

American-type sociology is distinguished by using induction from collections of observed fact rather than philosophical deduction. Its methods are thus more akin to those of the natural sciences than the methods of the sociology and economics mainly pursued in Europe. The facts observed may be opinions and attitudes; and one welcomes the first volume of the *International Journal of Opinion and Attitude Research*, edited by Prof. Radvany, of the University of Mexico, with contributions from H. D. Lasswell, Henry Link and Tom Harrisson. The facts observed may also be the behaviour of human beings one to another, and to study behaviour as well as attitudes, a new journal, Anglo-American rather than fully international, is being launched under the title of *Human Relations*. The first number contains an intriguing article by the late Kurt Lewin, a leader in sociological thought and technique as yet almost unknown in Britain. To an equilibrium economist his reduction of such social situations as unhappy marriages, restriction of industrial output or aggressiveness among boys to an equation of conflicting forces must be interesting and flattering. *Human Relations* also contains a survey of prejudice in a seaside town, and studies of the civil resettlement of British prisoners of war, and of a scheme for residential management in treating difficult children. The theoretical essays are thus well balanced by articles descriptive of current procedures. Occasionally, as in an unnecessarily complicated account of a fairly simple experiment in industrial training, the writing is wordy and pedantic.

The wide field of contemporary social activity now being approached in the scientific mood is clearly illustrated in these current periodicals. Quite apart from their admirable American articles, *Pilot Papers* contain in the two numbers for June and September 1947 a much-needed analysis of bureaucrat behaviour, of B.B.C. 'third programme' listening and of the conception of progress in general (by Dr. Julian Huxley) and its practice in agriculture in particular. There are also first-hand experiences of service on a jury, the 'closed shop', and rent tribunal procedure. We look forward to further numbers of all these ventures in modern sociology. P. SARGANT FLORENCE

NORTHERN IRELAND FISHING INDUSTRY DEVELOPMENTS DURING THE WAR YEARS

PRIOR to the outbreak of the Second World War, the inhabitants of Northern Ireland exported to Great Britain most of the fish they caught, and imported from Britain most of the fish that they ate. During the war years, however, the consuming public became much more dependent on their own locally caught fish and only surpluses were exported.

In a "Report on Sea and Inland Fisheries", recently published by the Government of Northern Ireland*, these and other war-time changes are reported. As no figures of production and trade exchange could be published during the War because of the statistical 'blackout', this report includes tables for the six-year period 1939–44.

The developments that took place in the Northern Ireland fishing industry during the years under review are indicated by the fact that herring catches in 1944, totalled 50,895 cwt. as compared with 39,467 cwt. in 1938, and whiting catches rose from 17,061 cwt. in 1938 to no less than 64,619 cwt. in 1944. The total value of fish (excluding salmon) landed on the coast in 1944 was £258,427.

Taking all kinds into account, the quantities of sea fish landed in 1944 increased to approximately double the pre-war figure. The total number of fishing boats in Northern Ireland was 508 in 1944, a decrease of 51 boats compared with 1938. Motor boats, however, increased from 314 to 338 in this period, and vessels solely engaged in fishing increased from 109 to 149 in 1944. The number of men employed in sea fishing increased from 898 to 1,031, of which latter figure 555 were whole-time fishermen, the highest number to be so engaged since the year 1930. The chief factor in this increase in the number of fishermen was the main County Down fleet, which increased from 45 vessels in 1938 to 56 in 1944.

The report states that the scheme of loans and conditional grants authorized in 1941, combined with greatly increased earnings by fishermen, gave the necessary incentive for the replacement of older craft by vessels of modern design. By the end of 1944, a substantial number of new craft designed for herring fishing and seine netting was either in commission or under construction in spite of war-time shortages. In the years covered by the report, loans exceeding £24,000 were advanced by the Ministry.

There is also a year-by-year review of inland fishing. Reference is made to the fact that in several hatcheries artificial propagation of salmon was carried out. The year 1943 was the best pollan season in Lough Neagh since 1927. High prices in cross-Channel markets greatly helped to stimulate the activities of the freshwater fishermen. On account of the scarcity of fish in Great Britain, considerable impetus was given to the capture of coarse fish in rivers and lakes in Northern Ireland. In the Lough Erne district alone, the total exports of coarse fish in 1944 increased to almost a hundred tons.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, March 22

ASSOCIATION OF APPLIED BIOLOGISTS (in the Botany Lecture Theatre, Imperial College of Science, South Kensington, London, S.W.7), at 11 a.m.—Discussion on "Biological Aspects of Water Pollution".*

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 5.30 p.m.—Dr. K. M. Strom: "The Geomorphology of Norway".

INSTITUTION OF THE RUBBER INDUSTRY, MANCHESTER SECTION (at the Engineers' Club, Albert Square, Manchester), at 6.15 p.m.—Mr. T. J. Meyrick and Dr. J. T. Watts: "Polyisocyanates—some Applications in Bonding".

Tuesday, March 23

MANCHESTER GEOGRAPHICAL SOCIETY (in the Geographical Hall, St. Mary's Parsonage, Manchester), at 6.30 p.m.—Miss K. Speight: "Sicily, the Garden of the Mediterranean".

TEXTILE INSTITUTE, LONDON SECTION (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 6.30 p.m.—Mr. F. Courtney Harwood: "The History and Science of Washing".

SHEFFIELD METALLURGICAL ASSOCIATION (at 198 West Street, Sheffield), at 7 p.m.—Dr. N. P. Allen: "Some Techniques and Results in Metallurgical Research".

Wednesday, March 24

BRITISH SOCIETY FOR INTERNATIONAL BIBLIOGRAPHY (at the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2), at 2.30 p.m.—Users' Questions on the Universal Decimal Classification Answered.

PALESTINE HOUSE (at 18 Manchester Square, London, W.1), at 5.45 p.m.—Dr. Clay Lowdermilk: "The Jordan Valley Scheme".*

ROYAL MICROSCOPICAL SOCIETY, INDUSTRIAL MICROSCOPY SECTION (at B.M.A. House, Tavistock Square, London, W.C.1), at 6 p.m.—Mr. H. L. Shipp: "The Microscopy of Food".

SOCIETY OF CHEMICAL INDUSTRY, NUTRITION PANEL OF THE FOOD GROUP (joint meeting with the BRITISH DIETETIC ASSOCIATION, at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Dr. D. P. Cuthbertson and Miss R. M. Simmonds: "Special Dietary Requirements in Sickness and Convalescence".

SOCIETY OF DYERS AND COLOURISTS, MIDLANDS SECTION (at the Victoria Station Hotel, Nottingham), at 7 p.m.—Mr. G. H. Lister: "The Absorption of Acid and Chrome Dyes by Wool".

CHEMICAL SOCIETY, ABERDEEN SECTION (joint meeting with the LOCAL SECTIONS of the ROYAL INSTITUTE OF CHEMISTRY and the SOCIETY OF CHEMICAL INDUSTRY, at Marischal College, Aberdeen), at 7.30 p.m.—Prof. E. E. Turner: "Some Stereochemical Problems".

Thursday, March 25

BRITISH INSTITUTION OF RADIO ENGINEERS, MIDLAND SECTION (at the Technical College, The Butts, Coventry), at 6.30 p.m.—Mr. N. E. Head: "Methods of Measuring the Insertion Loss, Phase-Shift and Time Delay of Transmission Networks".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned :

LECTURER IN ANATOMY—The Registrar, The University, Sheffield (March 27).

ASSISTANT MANAGER (DEVELOPMENT) (Ref. No. F.176/48), SHOP MANAGERS (DEVELOPMENT) (Ref. No. F.177/48), a SHOP MANAGER (CHEMIST) (Ref. No. F.178/48), and a SHOP MANAGER (PLANT MAINTENANCE) (Ref. No. C.131/48), in the Department of Atomic Energy, Springfields Factory, Salwick, Preston—The Ministry of Labour and National Service, Technical and Scientific Register, Room 669, York House, Kingsway, London, W.C.2, quoting relevant Ref. No. (March 30).

STATISTICIAN (No. A92/48A), and a STATISTICAL OFFICER (No. A461/47A), in the Air Ministry—The Ministry of Labour and National Service, Technical and Scientific Register, Room 669, York House, Kingsway, London, W.C.2, quoting relevant Ref. No. (March 31).

ASSISTANT DIRECTOR (PHYSICS)—The Director, Gas Research Board, 1 Grosvenor Place, London, S.W.1 (March 31).

SENIOR EXPERIMENTAL OFFICER in the Ministry of Supply, London, to supervise the valve interests of the Signals and Radar Research and Development Establishments and the secretariat of Inter-Service Technical Valve Committees—The Ministry of Labour and National Service, Technical and Scientific Register, Room 669, York House, Kingsway, London, W.C.2, quoting D78/48A (April 3).

SENIOR RESEARCH OFFICER IN THE BIOCHEMISTRY SECTION of the Division of Industrial Chemistry, Melbourne—The Secretary, Australian Scientific Research Liaison Office, Australia House, Strand, London, W.C.2, quoting No. 1623 (April 10).

SENIOR RESEARCH OFFICER IN THE BUILDING MATERIALS RESEARCH SECTION, Melbourne—The Secretary, Australian Scientific Research Liaison Office, Australia House, Strand, London, W.C.2, quoting No. 1618 (April 10).

ASSISTANT LECTURER (Grade III) IN GEOLOGY—The Registrar, Queen Mary College, Mile End Road, London, E.1 (April 15).

CHAIR OF GEOPHYSICS in the University of Istanbul—The Director, Personnel Department, British Council, 3 Hanover Street, London, W.1 (April 15).

CHAIR OF ANGLO-SAXON ARCHÆOLOGY at University College—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 16).

STATISTICIAN in the Department of Preventive Medicine—The Secretary and Registrar, The University, Bristol (April 17).

ASSISTANT LECTURER IN BOTANY (if possible with interest or experience in cytology and genetics), an ASSISTANT LECTURER IN ORGANIC CHEMISTRY, a LECTURER IN MATHEMATICS (with special qualifications in pure mathematics), ASSISTANT LECTURERS (2, one in Applied Mathematics and one in Pure Mathematics), an ASSISTANT LECTURER IN PHYSICS (preferably with experience in radar or geophysics), and an ASSISTANT LECTURER IN ZOOLOGY (preferably with experience in experimental cytology or genetics)—The Registrar, University College, Hull (April 17).

AGRICULTURAL ECONOMISTS (2), ASSISTANT AGRICULTURAL ECONOMISTS (3, Grade B), a LECTURER IN THEORETICAL PHYSICS, and an ASSISTANT LECTURER IN THEORETICAL PHYSICS—The Registrar, The University, Manchester 13 (April 17).

ENTOMOLOGIST in the Inter-Territorial Tsetse Reclamation Department, East Africa High Commission (Kenya)—The Under-Secretary of State, Colonial Office (Research Department), Palace Chambers, Bridge Street, London, S.W.1 (April 24).

LECTURERS (2) IN MECHANICAL ENGINEERING, and a LECTURER IN ELECTRICAL ENGINEERING—The Registrar, The University, Leeds 2 (April 24).

BRITISH COKE RESEARCH FELLOWSHIP tenable in the Department of Physical Chemistry—The Registrar, King's College, Newcastle-upon-Tyne (April 30).

TURNER DENTAL SCHOOL RESEARCH FELLOWSHIP, and the INTERNATIONAL WOOL SECRETARIAT SCHOLARSHIP—The Registrar, The University, Manchester 13 (April 30).

PROFESSOR OF BACTERIOLOGY in the University of Queensland—The Agent-General for Queensland, 409 Strand, London, W.C.2, or the Secretary, Universities Bureau of the British Empire, 8 Park Street, London, W.1 (Brisbane, May 31).

LABORATORY TECHNICIAN (Grade B.1, histological technique essential) IN PATHOLOGY DEPARTMENT—The Secretary, Welsh National School of Medicine, 10 The Parade, Cardiff.

AGRICULTURAL ECONOMIST, an ASSISTANT AGRICULTURAL ECONOMIST, and a DEMONSTRATOR IN PHARMACY—The Registrar, University College, Nottingham.

TECHNICAL ASSISTANT to assist in steelworks investigations, mainly in connexion with ingots and moulds—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1, quoting 'Ingots'.

SENIOR LABORATORY STEWARD—The Secretary, Northampton Polytechnic, St. John Street, London, E.C.1.

ASSISTANT BACTERIOLOGIST IN VACCINE LYMPH DEPARTMENT—The Bacteriologist-in-Charge, Lister Institute, Elstree, Herts.

MOBILITY OF MAN-POWER IN BRITAIN

THE broadsheet "Man-power Movements" (No. 276), which Political and Economic Planning issued in January, develops further a theme on which an earlier broadsheet, "Framework of Collective Bargaining" (No. 272), published in October, had touched slightly ; a theme the importance of which has been accentuated by the growing seriousness of the economic situation of Great Britain. The existence of that crisis was not clearly recognized when the "Economic Survey for 1947" (Cmd. 7046) was issued, and even now the imminent risk of a further and still more serious reduction in our standard of living is not widely appreciated. Too little is still known, as this new broadsheet reminds us, about productivity ; it is recognized that redistribution of man-power is essential in order to realize the projected investment and consumption programmes, but the point is clearly made that man-power movements alone are insufficient. Economic planning is equally a matter of management, machines, materials, money and, as the broadsheet says pointedly, ministries ; and the value of man-power policy depends on its appropriateness in relation to other policies and to their general aim, which must contribute towards keeping the economy in balance.

What should be remembered in considering the Control of Engagement Order, 1947, is that no steps were taken in 1945–46, comparable with the measures adopted in war-time, to see that workers went where they were most likely to be needed. Serious political difficulties would have been involved in any attempt to guide more positively the flow of labour from the Armed Forces and from war industries. Various measures of control were, however, retained for a time over the movements of coal-miners, agricultural, building and textile workers, nurses and Civil servants. The real gravamen of the criticism of the policy then adopted is that the public was not made to realize that wider measures of control might be necessary, and nothing positive was done to correct the dangerous tendencies. The smoothness of demobilization was, indeed, partly due to the fact that workers were going where they wanted to go, irrespective of where they might be most needed ; and even the Economic Survey for 1947, in noting the shortage of workers in coal-mining, textiles and agriculture, did not face the fact that transfer from, or restraint of expansion in, other industries might be necessary.

The *Planning* broadsheet maintains that neither the premature exhaustion of the United States loan nor the further deterioration in the terms of trade altered the situation so drastically between February and September 1947 that planning could not last year have been visualized as a problem of securing the acceptance of uncomfortable measures necessary to realize the plans. The main problems of man-power were recognizable two years ago, and very slow progress has been made towards solving them. The present requirements are, first to effect an immediate improvement in the 'bottle-neck' industries; next to expand production (as distinct from productivity) in industries devoted to exports, import substitutes and certain consumer goods; thirdly, to increase the output per man-hour so far as the concentration of investment on the second permits, and where necessary to increase hours of work; and last, to restrict production in those industries which compete for labour and raw materials with the industries already indicated.

In regard to the first, P.E.P. considers that it is doubtful whether enough has yet been done to solve the problems of 'bottle-neck' industries through a more efficient use of their products. There are two other methods of adjusting deficiencies in such industries without inter-industrial movements of man-power. Output per man hour could be increased by better organisation of production by managements, the use of more or better machinery or by a voluntary increase in effort due to improved worker – management relations, national appeals or material incentives—improved quality of the products could also help—but if these methods fail, the working of longer hours may be necessary as a last resort.

Dealing then with the size of the problem, the broadsheet maintains that the whole concept of an absolute, general shortage of labour is dangerous and misleading, tending to distract attention from the fact that the targets are too high and from the need to increase productivity. Furthermore, it points out that difficulties arise not from the fact that large numbers are required, but from the unattractiveness of the jobs, and from such problems as housing in areas where industries urgently need workers. It raises the question whether the Control of Engagement Order should ever have been imposed, even if it were certain that it would solve the immediate problem. Political and Economic Planning maintains that the present problem is exceptional only in degree, not in its nature, and that the maintenance of 'full employment' will always necessitate measures to combat the rigidity of labour distribution. Finally, it attributes the distortion of the labour structure from the pattern dictated by present needs primarily to the fact that for many years Great Britain has been enjoying a substantial proportion of free imports.

Nothing less than the whole future of 'full employment' in Britain is at stake. The broadsheet directs attention to the importance of the workers having complete confidence in the security of employment if mobility is to be secured; and it makes its most important point in insisting here that it is necessary to convince workers also that a degree of mobility between industries is permanently needed if full employment is not to prejudice the efficiency and adaptability of the economy. A fresh approach should be made by the whole Government public relations service, with which the National Joint Advisory Council should co-operate to the full. Labour controls cannot provide the answer to the long-term problem of distributing labour, and some method must be found which will be flexible. efficient, secure, and retain the confidence of both employers and workers, and make use of the natural motives and incentives normally influencing the individual. Our lack of knowledge about these motives and incentives makes the need for research and experiment only the more urgent.

One field for research suggested in the broadsheet is a study of the high degree of mobility which appears to exist among the professional and managerial classes; such a study might yield valuable information for the basis of an incentives policy, which is as essential as some sort of wages policy. Again, the need for research into the statistical, geographical, industrial, social and psychological factors affecting labour distribution and mobility is urgent. The results of the research should be given the widest publicity. There may well be great scope in this field for the British Institute of Management, though official initiative is also important; *Planning* welcomes the recent establishment of a Scientific Committee on Industrial Productivity. One of the most urgent needs is for an inquiry to supply the data on the occupational distribution of the population which would have been provided by the Population Census of 1941. The public needs the fullest possible basis of knowledge to enable judgments to be made on the man-power problems of full employment, and no one concerned to see public policy guided by knowledge and reason rather than prejudice should fail to support P.E.P. in its contention or to press on the Ministry of Labour the opportunity it has there, since the control and co-ordination of the strategy of man-power planning must be centralized in its hands.

The account of collective bargaining which P.E.P. offers in its broadsheet on this subject (No. 272) as a contribution to public understanding is valuable, and forms one of a series of studies in British trade unionism being published. It is primarily factual and descriptive, and brings up to date material contained in the Industrial Relations Handbook published in 1944 by the Ministry of Labour; but it also covers certain subjects, such as wages councils, which are not included in that Handbook. It thus helps to fill the need for a comparatively simple guide to the main varieties of collective agreement and the way in which they have developed.

The broadsheet shows that nearly 90 per cent of the insured workers of Great Britain are covered by negotiating machinery of one kind or another, and of these about one third are in six great key industries, all of which have developed their own characteristic machinery on a voluntary basis. Another third are in industries covered by the Whitley system of national joint industrial councils. The admirable description of this system is the feature of the broadsheet of most interest to the scientific worker; although there is no discussion of the problems arising out of the association of the professional worker or manager with such bodies. The remaining third are covered by statutory wage-fixing machinery; this section of the broadsheet deals with the Wages Council Act of 1945, which renamed and reorganised the old Trade Boards.

Both broadsheets 272 and 276 emphasize the point made in an earlier broadsheet on "The Plan and the

Public", and which Sir Oliver Franks brought out so well in concluding his Sydney Ball Lecture, "The Experience of a University Teacher in the Civil Service", regarding the vital importance of public relations work in securing effective co-operation. Unless the generalities in which Government economic policy is contained can be effectively interpreted and communicated to those required to help in carrying out the policy, methods of reason may break down. The chief responsibility for setting policies before the public must rest with Ministers. But some responsibility must also rest upon Civil servants in their many dealings with the public, and on management. It will often depend on how they expound and administer a policy whether the conception of something 'we' are committed to carry through replaces that of something 'they' have ordained.

ORIGINS OF SPECIES AND MIGRATIONS OF FLORAS

The Genus Crepis

By Ernest Brown Babcock. (University of California Publications in Botany, Vols. 21 and 22.) Part 1: The Taxonomy, Phylogeny, Distribution and Evolution of Crepis. Pp. xii + 198. 3.50 dollars. Part 2: Systematic Treatment. Pp. x + 199–1030 (36 plates). 10 dollars. (Berkeley and Los Angeles: University of California Press; London: Cambridge University Press, 1947.)

THE appearance of Babcock's monograph after four years delay in the press, due doubtless to the War, is an event of considerable importance, not only to botany but also to the biological sciences in the widest sense. Familiar as are parts of it to specialists, through the publication of numerous papers during a period of over twenty-five years, the collation of all this work in monographic form should bring it into the hands of a far wider circle of readers.

Part 2, the larger portion, resembles at first sight a systematic monograph of the ordinary type. It contains the morphological background to the cytogenetic work obtained by the use of all the ordinary criteria available to taxonomy; for example, comparison of herbarium specimens, collation of literature, etc., illustrated by outline drawings to a uniform scale of almost all the 185 species which are described. It contains, however, far more than this. For the first time, in a work of this magnitude, cytogenetic information on a scale unknown in any other group of plants or animals, not even excepting *Drosophila*, is included. It is true that from the point of view of pure genetics individual species such as *D. melanogaster* or *Zea Mays* far exceed anything which has yet been attempted in *Crepis*. We have here, on the other hand, a cytological record, in many cases amplified by genetical information derived from inter- and intra-specific crosses, of no less than 113 species of a monophyletic genus which spreads from Eurasia to Africa and America, a genus, moreover, which is exceptional among plants for the low number and large size of its chromosomes. Full credit is given in the introductory paragraph to Part 1 to the early work of Rosenberg, Juel and Digby, who first detected $n = 3$ in *Crepis capillaris* and $n = 4$ in *C. tectorum*. To Babcock is due, however, the credit of recognizing the importance of low chromosome number in 1915, and for having stimulated by his exertions not only a numerous school of collaborators in the United States, but also some outstanding cytological workers in the Old World, notably the Russian school under Nawaschin. The result is a display of cytological information which has never previously been equalled and which will long remain unsurpassed. The incorporation of this knowledge in the systematic monograph places it at once in a class apart.

Scarcely less important are the geographical data included in the numerous distribution maps appended to the various sections of the genus. Until quite recently information about the floras of large tracts of country, notably in central and north-eastern Asia, was so meagre as to preclude an effective treatment of the plant geographical development of the floras of the northern hemisphere considered as a whole, with the result that an over-emphasis on Europe led to very widespread misconceptions on the order and importance of events which are only now becoming apparent. Recent phyto-geographical exploration of these missing regions, notably by Hultén[1], is profoundly altering previous concepts, and it so happens that north-eastern Asia turns out also to be of fundamental importance in the evolution of *Crepis*. The collation of the geographical evidence on plant migrations with the cytogenetic evidence on the order of evolution of species is not the least important part of the whole work. The detailed discussion of endemism in this context, enriched with the certain knowledge as to which endemics are relics and which innovations, knowledge which is impossible without the type of cytogenetic and morphological data here assembled, also enables the author to discuss not merely plant migrations and the origin of the floras of four continents, but also cognate matters such as the theory of 'age and area', with effectiveness and, in part at least, with the semblance of finality.

These matters are dealt with in Part 1 of the work under review, and their close perusal is much to be recommended to geographers, zoologists and botanists interested in other groups inhabiting these regions. Part 1 also contains, among other things, the summary of the main cytogenetic conclusions on the mechanism of evolution in *Crepis*, a statement which may profitably be amplified for the general reader by perusal of a still more recent summary by Babcock in another connexion[2]. From the analysis of 113 species and very numerous interspecific hybrids, *Crepis* is seen to be a genus which, on the whole, has evolved with little aid from polyploidy and by a process of reduction rather than increase in chromosome numbers. Polyploidy has affected less than 8 per cent of species. Interspecific hybridization has been involved in some 20 per cent of species, and primary importance has to be assigned to the internal action of segmental interchange and genic mutations, aided by genetic, geographic or ecological isolation, in making possible the morphological and physiological differentiation of the rest. Detailed information is provided about the mode of operation of both the latter processes in the speciation of various parts of the genus, and the importance of work such as that of Tobgy[3] and Gerassimowa[4] in revealing how segmental interchange can alter chromosome morphology and set up sterility barriers without other genetic changes is very clearly brought out, especially in Babcock's later article[2], and in doing so a very important gap in our knowledge of evolutionary mechanisms is partially filled, with fact instead of surmise.

Finally a survey is given of the numerous outstanding lines of work which could be further pursued with profit. It is to be hoped that this work will indeed be continued, and this seems the more probable in that it has already been supported for more than a quarter of a century by a State (California) Agricultural Research Station, although *Crepis* is a genus of no economic importance. It is fitting to express appreciation of such an enlightened policy, and the world is no less indebted to the University of California for providing in its "Publications in Botany" a medium admirably suited in format and style to the issue not only of individual research papers of the usual kind, but also to an extended work of pure scholarship of the dimension of a large book such as that under review. International co-operation and disinterested support of fundamental research on this scale cannot easily be found even to-day in this age of planned science, and this is perhaps not the least important of the issues raised by Babcock's work. RADIOELEMENTS AS A TOOL IN SCIENTIFIC RESEARCH

Radioactive Tracers in Biology

An Introduction to Tracer Methodology. By Prof. Martin D. Kamen. (Organic and Biological Chemistry, a Series of Monographs, Vol. 1.) Pp. xiii+281. (New York: Academic Press, Inc.; London: H. K. Lewis and Co., Ltd., 1947.) 5.80 dollars.

AT the beginning of this century, one of the facts most intriguing to chemists was the impossibility of concentrating some of the radioactive elements. Radium D, for example, a substance well characterized by its radioactive properties, proved to be completely inseparable from the large quantities of lead with which it was always burdened when extracted from minerals. Early in 1913 it was realized that the strange inseparability observed in radiochemistry, and the atomistic complexity of inactive elements as revealed by mass spectroscopy, were aspects of one and the same phenomenon, for which the new Rutherford–Bohr theory of the atom provided a convincing explanation. But even before this recognition of the nature and importance of 'isotopy', attempts had been made to turn the negative results of the separation experiments into a positive service to science: the solubility of sparingly soluble lead salts was determined by mixing them with radium D and using the imparted radioactivity for the electroscopic measurement of the invisibly small quantities of dissolved lead.

In those days there were only half a dozen or so suitable radioelements available, all of them in the last two rows of the Periodic Table. Therefore, 'radioelements as indicators', while a great help for a variety of investigations in inorganic and physical chemistry, were scarcely applicable to biological experiments—although so early as 1923 G. von Hevesy made some interesting observations about the intake of lead by plants by means of such an indicator. For the most important biological elements like carbon, hydrogen, oxygen, phosphorus, sulphur, or sodium, unfortunately no radioactive isotopes were known. Now the 'labelling' of an element should be possible also with inactive isotopes, though the methods of their detection and measurement are necessarily different and, in general, less simple; but in those days this way was barred too, as no means were known of preparing the inactive isotopes in more concentrated form than they occur in Nature, let alone in a pure state.

To-day in both directions the situation has completely changed. The discovery of the artificial radioelements in 1933 soon made radioactive isotopes of most of the elements available, and the development of several methods for isotope separation also put inactive atomic species at the disposal of scientific workers. As a consequence, the use of 'tracers', as they are now usually called, became a much more important practice in biological as well as non-biological research. Of special influence in this development was the erection during the War of big plants in the United States for isotope separation and for plutonium manufacture, the products and by-products of which can now be used for peaceful purposes. Similar plants will soon be operating in Great Britain and Canada; but in the meantime the American Government is willing to provide scientific workers all over the world with the invaluable materials, under the same conditions as laid down for American laboratories.

In these circumstances, many scientific workers who have otherwise no contact with radioactivity are anxious to make themselves acquainted with the powerful new method. By far the best way is, naturally, a course of instruction in one of the radioactivity centres; but as the principles of the method are simple, and the apparatus as well as the tracer material can be bought, training by books is certainly possible. It is therefore a pleasure to find that an excellent guide to the tracer technique with radioelements has been published by one of the most successful workers in this field. Prof. M. D. Kamen calls his manual "Radioactive Tracers in Biology"; but he is so thorough in making the reader well acquainted with the physical and chemicals aspects of radioactivity and with the theory of the measuring instruments before discussing biological applications, that those who intend to use radioactive tracers for non-biological research will also find in the book a wealth of useful information. In points of detail there may be some disagreement. Thus the author defines 'specific activity' (p. 33) as the ratio of the number of radioactive isotope atoms to the total number of isotope atoms; while later (p. 152) he uses as specific activity the number of counts per minute per milligram. Most workers in this field will probably prefer the second definition; and they may also not share the author's predilection (p. 91) for the term 'rutherford' instead of 'curie' (compare, *Nature*, **160**, 778; 1947).

Biologists will find the final chapters of particular value, for here the author deals, one by one, with the principal radioactive tracers as applied to metabolic studies. Very frequently he can draw on personal experience, and his descriptions display all the freshness which only first-hand knowledge can impart. In conclusion, we would like to express the hope that the other branches of radioactive and inactive tracer methodology will soon find authors as competent and literarily gifted as Prof. Kamen has proved himself to be in the very important field he has chosen as his own. F. A. PANETH

ECOLOGICAL PROBLEMS OF THE HIGHLANDS AND HEBRIDES

Natural History in the Highlands and Islands

By Dr. F. Fraser Darling. (New Naturalist Series.) Pp. xv+303+64 plates. (London and Glasgow: Wm. Collins, Sons and Co., Ltd., 1947.) 16*s.* net.

THIS is a notable book about Scotland north and east of the Highland Border Fault, where much that is wonderful and unique in Nature still flourishes; its case for a new deal for the Highlands and Hebrides, because it is developed on detailed ecological considerations, and its humanism (without 'bogus romance'), also make it a different kind of book. The author, rightly esteemed for his biological researches in the region and for his present labours as director of the West Highland Survey, is almost certainly the one man possessing the qualifications to attempt it.

The first three chapters deal with geology, climate, relief and scenery, the other nine with human and animal factors: forest, moor and farm; hill summits; shore, sea, loch and shallow seas; islands; fresh-waters; red deer; grey seal; and reflexions on main issues. There follow a long bibliography, index and fifteen distribution maps by Dr. James Fisher.

The book merits the compliment of searching criticism. The reviewer and biological colleagues agree that, much though they welcome its advent, a longer gestation and more consultation with specialists would have given it better proportion and minimized the number of blemishes. The citation of even typical slips and errors regarding altitudes, distribution, nomenclature, cross-references, etc., would occupy too much space here; such will be communicated to the author. Those using the book scientifically require, therefore, to be warned of the necessity for checking details by reference to authoritative sources.

Certain matters of printing craft cannot be so passed over. The plates, mostly, are original and very attractive; everything possible has been done with many of the coloured photographs, but it is disconcerting to see two-colour plates (18 and 23, review copy) half an inch out of register. Regarding the black-and-white illustrations, perhaps the paper used is the best obtainable now; but it does not appear to be the most suitable, the plates often being flat and dense (for example, III, review copy). Another copy shows duplication of bibliography, one index page, and maps.

The sentiments and style of the fine concluding chapter deserve applause. The author speaks of his loved country "with its power, colour, variety and movement; the diversity of living forms and the delicacy of their inter-relations"; of its sufferings and despoliation following the two revolutions that struck it—the coming of the sheep after the destruction of the forests, and the delight in game preservation which practically meant the killing of common mammals and birds without reference to their life-history. "Let us," he says, "give beast and bird and flower the place to live *in its own right* unless pest or obnoxious parasite."

What is being done about it all? Promise of much lies in the concern expressed by those in high place (the Secretary of State for Scotland and others) for schemes of forestry, national parks, crofting and hydro-electricity. But progress would be speeded and intensified by the co-ordination of such schemes, by the education and "active work of ordinary folk, of people who visit the Highlands and of those who live there"; and, with all this good will, by the institution of "a trained wild-life service, a corps of men working on natural history, studying phenomena and forecasting consequences and gaining a knowledge of the dynamics of natural populations".

Despite its shortcomings of detail the book is a gallant effort, much needed, stimulating and highly successful. Its appreciation by the reviewer and a colleague (neither Scottish) is measurable by the fact that between them they bought a dozen copies as gifts to laymen and younger naturalists.

A. D. PEACOCK

POLITICAL TESTAMENT OF AN ANTHROPOLOGIST

Freedom and Civilization

By Bronislaw Malinowski. Pp. xiv+338. (London: George Allen and Unwin, Ltd., 1947.) 16*s.* net.

BRONISLAW MALINOWSKI died in the United States in 1942 leaving a number of unfinished manuscripts in various stages of development. Two of these, "A Scientific Theory of Culture" (reviewed in *Nature* of August 25, 1945) and the present work, to some extent overlap. "Freedom and Civilization" may be regarded as a war-time political manifesto superimposed on the body of anthropological theory expounded in the earlier volume. This topical quality is manifest in the introductory section, "Political Prelude", and in the first chapter of Part 2 entitled "What we are fighting for". It is therefore unfortunate that the book-wrapper of the present English edition should give the impression that the book is an 'objective' contribution to political philosophy.

Objectivity was never Malinowski's method. Like all great teachers, he was prone to generalize recklessly from a special instance in order to drive home a point of principle. Some of the categorical assertions of this book are startling and would be hard to justify by any 'objective' criterion; for example, "a regular, systematic or tyrannical abuse of authority is not to be found under primitive conditions" (p. 118), or "in primitive communities the magician . . . always inspires the community with a consciousness of discipline and with the faith in leadership" (p. 213), or again, "headhunters and cannibals cannot loot because there is no portable or accumulated wealth at that stage" (p. 281). But such statements seem to me to be not so much unverifiable assertions as decorations to the general argument.

This argument is the declaration of a political *credo*, a statement of liberal positivist faith in the human spirit which belongs to the tradition of J. S. Mill's treatise "On Liberty" or Condorcet's "Esquisse d'un tableau historique des progrès de l'esprit humain". The latter perhaps is a particularly appropriate parallel, for it was written in the war-time Paris of 1793, a few months before its author's death.

Approximately one third of the book is devoted to a critical examination of the concept of freedom, and to the selection of a range of meaning for this emotionally overloaded term which will satisfy the author's requirements. This long discussion of what is largely a problem of semantics could with advantage have been well pruned in final draft. The sequence of the argument thereafter appears to rest on the following set of premises: (*a*) the concept of freedom can only be judged against a background of fundamental human needs which are served by the necessary restrictions on the individual imposed by human culture (pp. 89, 100); (*b*) the evolution of the practice of warfare since archaic times is manifested in the culturally defined behaviour of various grades of modern 'primitives' (Part 5, Chapter 5); (*c*) the Anglo-Saxon concept of democracy, as interpreted by Malinowski (p. 231), is a logical development from the ideology of "the earliest human cultures known to anthropology"; (*d*) the mutual interaction of institutions in a primitive 'tribe-nation' is normally such as to inhibit the development of civil war (pp. 262, 279); (*e*) totalitarian political organisation is an aberration from the normal because it has, as its inevitable concomitant, total war, which is a civil war within the body politic of world civilization (pp. 293, 309, 317).

To achieve this 'scientific proof' of the villainy of Hitlerism is something of a *tour de force*. In the context of 1942 it was perfectly justifiable; but it needs to be stressed that resort is had to some very question-begging definitions and assumptions. The important argument on pp. 252–255, which insists that 'a tribe' can be equated with 'a culture', and that such discrete units are always readily identifiable on the ground, strikes the present writer as highly questionable. Or again, the restriction of the meaning of 'war' to "an armed contest between two independent political units carried out by means of organised military force in the pursuit of a tribal or national policy" (p. 277) leads to the somewhat artificial inference that the aggressive activities of "the lowest primitives . . . headhunters and cannibals cannot be regarded as real war" (pp. 277, 281); moreover, by implication, they cannot be regarded as civil war either (pp. 281, 293). But by much the same argument a pedant might argue that the current unpleasantness in Greece and Kashmir is also neither real war nor civil war.

Another consequence of the political objective of the book is that the anthropological content is backed up by evolutionary doctrines which no longer find any place in ordinary anthropological academic discussion. As a teacher, Malinowski was always at pains to stress that the speculative reconstruction of long-term history could form no part of a scientific anthropology, and it is a shock to find him here discussing various groups of modern primitives in strictly parallelist evolutionary terms. But though the attempt to blend anthropological theory and political philosophy is not entirely successful, it raises wider issues. Anthropological acclamation of freedom is no novelty. So early as 1843 Klemm conceptualized the three stages of human progress as *Wildheit*, *Zahmheit* and *Freiheit*. The social scientist can never hope to be entirely detached, and it is arguable how far he can, or should, avoid imposing his own value-judgments upon the material of his study. My own feelings, in the present instance, are that it would need only a slight recasting of Malinowski's argument to demonstrate that totalitarian Russia rather than democratic America is the true heir to the 'proto-democracy' of archaic primitives, and this makes me suspicious of the whole procedure. Yet in some ways the attempt is magnificent. Towards the end of his book Malinowski claims that "the scientific indication of freedom attempted in this analysis vindicates all our personal preferences, the dictates of our common sense, and of our moral sense also, since it shows in cold dispassionate analysis that our democratic regime is a sound mechanism of progress, while totalitarianism must inevitably kill not only freedom, but also the gift which it has given humanity, that is, culture" (p. 317). The analysis is neither cold nor dispassionate; yet it is dogmatic optimism of this sort which will one day make possible a true humanist civilization.

E. R. LEACH

HISTORY OF ANÆSTHESIA

Victory over Pain

A History of Anesthesia. By Dr. Victor Robinson. Pp. xiv+338+30 plates. (London: Sigma Books, Ltd., 1947.) 16*s*. net.

THE discovery of anæsthesia, the centenary of which has just been celebrated, was one of the most important happenings in the history of mankind. The publishers of the volume under notice did well to produce it with such care and in such satisfying style; Dr. Robinson has appreciated the magnitude of his task and has magnificently overcome many of the difficulties that beset the historian of his subject. Indeed, the first two thirds of his book are excellent. Rapidly reviewing and rightly dismissing the stories of classical and medieval 'anæsthesia', he describes the unhappy years between 1799 and 1846 in graphic studies of Davy, Hickman and Wells, each of whom scored a 'near miss' on the target of painless surgery. Then follows the triumphal story of Morton's demonstration on the morning of October 16, 1846. This was a tremendous event; Dr. Robinson presents it calmly but with firm insistence on its importance. There follow descriptions of Jackson, the would-be 'spiritual father' of the discovery, and of Long, who had practised etherization as early as 1842 without troubling to inform a pain-racked world. These are a mild anticlimax as compared with the actual descent from the heights into the infamous and damnable 'ether controversy' which arose between Morton, Jackson and Long. As a storyteller, Dr. Robinson is no doubt right to dismiss what is beneath contempt as also beneath notice; as a historian, he is wrong.

It appears that we have heard too much of how Simpson over-stated his claim to be the 'discoverer' of chloroform (and, by an implication natural in Great Britain, of anæsthesia itself). Dr. Robinson treats these pretensions very gently indeed; so much so, that we are scarcely surprised later to find that Benjamin Ward Richardson is given more space and praise than the recorded facts would seem to justify. ("Is there no offence in't ?" "No offence i' the world.") New matter, new at very least to histories of anæsthesia, appears in the account of Samuel Guthrie, the backwoods chemist who apparently should share the chloroform glories of Dumas, Liebig and Soubieran. Dr. Robinson proceeds to develop his general theme by particular accounts of the men who led the way. Excellent though this method was in the beginning, it is hopelessly inadequate as the subject expands and ramifies. So many men took part in discovering agents, devising instruments and developing methods that there is no middle way between a catalogue of names or an inconsequent selection; in this instance we are presented with the latter.

In the end, Dr. Robinson gives us an inadequate description of anæsthesia's newest ally, the muscular relaxation obtainable by the use of curare. This is followed by a rhapsodic and almost incoherent epilogue of praise and exhortation. Had the author contented himself with describing pre-anæsthetic days and the events which led up to the discovery of ether anæsthesia, he would have given us a notable work. We have, however, one which starts well, continues magnificently, but ends in an inconclusive and aimless flurry.

G. Edwards

PURE AND APPLIED SEISMOLOGY

When the Earth Quakes

By the Rev. James B. Macelwane. (Science and Culture Series.) Pp. xiii+288. (Milwaukee: Bruce Publishing Co., 1947.) 5 dollars.

In 1944 the Institute of Geophysical Technology was established at St. Louis, U.S.A.; in co-operation with the University, and Father Macelwane was chosen as its dean. For one so well versed in the basic subjects of geology, physics and mathematics, this was a well-merited honour; and in so short a time as 1944–47 dividends have been paid. "By their fruits ye shall know them" has been well borne out, for out of the St. Louis Institute of Geophysical Technology, based on work by J. J. Shaw in England, has come the new use of the seismograph as a meteorological instrument via the study of microseisms by Father Ramirez. Father Macelwane and his colleagues at St. Louis are about to take this work a step further by setting up sensitive microbarographs at the angular points of a triangle of several hundred feet side in order to trace the paths of microbarographic storms, and for this work the weather-minded U.S. Navy has assisted with a grant of 25,000 dollars.

After writing so many technical papers and books on geophysics and its associated subsidiary subjects, Father Macelwane, while in the midst of his work, has at last been persuaded to write a book on seismology for the general reader. Seismology deals not only with earthquakes as they are felt, but also with the nature and causes of earthquakes and their relation to other geological processes in the earth. It deals with the effect of earthquakes on structures built by man and with all the problems of engineering that arise from them. It includes the physics of earthquake waves propagated through and round the earth, and the knowledge these give us of the earth's interior. It treats of man-made earthquakes, the vibrations caused by blasts of explosives, and their use in determining the hidden make-up of the earth's outer shell, thereby assisting in the location of valuable mineral deposits, especially petroleum. The book covers the whole field of pure and applied seismology, and Father Macelwane is to be congratulated on compressing so much material, while keeping it readable, into so small a space. Many natural earthquakes, their supposed causes and their effects are described, together with the manner in which they are studied macroseismically in the field and by means of instruments. Sea quakes and seismic sea waves are discussed, and there is a chapter on earthquake noises following Davison. The engineering aspect in such subjects as earthquake-proof design is not overlooked, and there are chapters on rock bursts and also on seismic prospecting.

A glossary is provided to enable the reader to come to grips with some technical terms, and this will undoubtedly help. There are a full list of references in addition to acknowledgments, and a good index. The text is interspersed with numerous good clear diagrams as well as photographs as illustrations in a book which is a joy to handle after the 'austerity' books of present-day Britain.

E. Tillotson

ARCHÆOLOGY AT OXFORD

Archæology and the History of Europe

An Inaugural Lecture delivered before the University of Oxford on 28 November, 1947. By Prof. C. F. C. Hawkes. Pp. 24. (Oxford: Clarendon Press; London: Oxford University Press, 1948.) 2*s.* net.

It is indeed excellent that the University of Oxford has created a chair of European archæology, and that Christopher Hawkes has been selected as its first occupant. The University will gain lustre from his learning, and he will have scope to work out in practice the very definite ideas about the orientation of his subject which he sets forth in this lecture. It is indeed well that the various universities interested in archæology should not all place it in the same setting or look at it from the same point of view. Prof. Hawkes says, for example, that archæology "is not a subject in its own right, as are History, Philosophy, or, say, the Biological Sciences". As a Cambridge archæologist, I can only ask, "Why not ?" Biochemistry is considered as a separate subject, and yet it only recently hived off from its parent sciences. Prehistory and archæology have similarly hived off from geology and early history, but surely can by now be classed together as a single subject worthy of an honours school.

Again, Prof. Hawkes says that for him archæology belongs to history, not simply in operational practice but in philosophical theory likewise. It is excellent that this aspect of the subject should not be forgotten, and Oxford is probably the appropriate place where it should be particularly enunciated. But there is also the possibility that archæology—more especially in its early phases—can be considered scientifically, and that it is the scientific approach to the subject which should be stressed and which indeed adds much to its charm.

As was to be expected, Prof. Hawkes has given a most interesting and thought-provoking inaugural lecture, couched in the inimitable literary style we have come to expect from him and his University, and enlivened by some charming touches, as when he self-deprecatingly refers to himself as being pegged out over so large an acreage of professorial territory that he fears his thinly outspread vitals will offer but little sustenance to the birds ! But when we have considered his ideas on the scope and disciplines and duties of his subject, we can only reassure him that his fears are groundless. We look for great things from him in this new chair with his particular way of surveying his domain. For the last thirty years the Cambridge school has stressed the scientific and anthropological approach to archæology : it will be interesting and valuable to see a school grow up at Oxford on the lines suggested in this lecture. If our sister university is late in the field with her chair, she could not have dignified it with a more happy choice of a first occupant.

Miles Burkitt

Microcalorimetry

By Prof. W. Swietoslawski. Pp. x+199. (New York: Reinhold Publishing Corporation, 1946.) 4.75 dollars.

THE author is professor *in absentia* of physical chemistry of the Institute of Technology, Warsaw, and senior fellow, Mellon Institute, Pittsburgh.

In the monograph under notice he reviews the methods which have been used for measuring small amounts of heat. Such methods find application in physics, physiology and kindred subjects. The reader will find it a valuable reference work when faced with a problem in micro-calorimetry, for in successive chapters information is given on the micro-calorimeters used in radiology; the use of the ice calorimeter in microthermal measurements; calorimetry of processes of short duration; adiabatic micro-calorimeters; and labyrinth flow calorimeters. To facilitate references to original sources of information, the author has collected 130 references to published work on the subject.

Throughout the book, stress is laid on the value of comparative measurements. Such methods may involve: (1) using twin calorimeters and in compensating the heat developed in one calorimeter by electrical energy introduced into the other; (2) carrying out two successive measurements in one calorimeter, so as to produce the same thermal effect by an electric current as that developed by the object under examination; (3) using two series of successive measurements as mentioned above, with the difference that in one experiment the heat is developed by the object only, and in the other by the object and an electric current; (4) comparing the heat liberated by the object with that produced by a standard substance. The use of all these methods is described in the book.

The author has had an extended experience in the development of micro-calorimeters, and his critical comments on the various designs constitute a substantial contribution to the subject.

EZER GRIFFITHS

Between the Planets

By Fletcher G. Watson. Pp. v+222.

The Story of Variable Stars

By Leon Campbell and Luigi Jacchia. Pp. v+226.

Galaxies

By Harlow Shapley. Pp. vii+229.

(Harvard Books on Astronomy.) (London: J. and A. Churchill, Ltd., 1947.) 18*s*. each volume.

THESE three volumes belong to the well-known series of Harvard Books on Astronomy. The first and second were published in 1941, the third in 1943; reprints of all three have been required, and some additions have been made to the second. The Harvard College Observatory is to be congratulated on its enterprise in arranging for the publication of a series of eight books, all by members of its staff, which together provide a comprehensive and up-to-date survey of astronomy. Each book is written by an authority in its particular field, is abundantly illustrated, and is well printed. The series has gained a well-merited success. Though intended primarily for students, teachers and amateurs, the books are useful also to the working astronomer for reference purposes, as recent developments in the respective fields are dealt with.

The first of the three volumes under notice is concerned with the minor planets, comets, meteors and the zodiacal light. The second deals with variable stars, including novæ and eclipsing variables. The third includes a detailed account of the Magellanic Clouds, of the Milky Way considered as a galaxy, and of the neighbouring galaxies; the more remote galaxies are then dealt with, and finally the problem of the interpretation of the red displacements of the lines in the spectra of the distant galaxies is discussed.

H. S. J.

A Text Book of Physical Chemistry

By Dr. N. C. Sen Gupta and K. C. Sen. New edition. Pp. xv+526. (Calcutta: Mondal Brothers and Co., Ltd., n.d.) 10 rupees.

THIS is an interesting survey of physical chemistry up to the pass B.Sc. standard and a little beyond in places. It deals with the usual subjects, thermodynamics being given special prominence. In the section on electrolytes, activity coefficients are developed and used, and the treatment is modern. The sections on atomic and molecular structure are good. There are collections of questions and problems, with answers, and suggestions for further reading.

Although intended primarily for Indian students, this book is a very useful review of modern physical chemistry in reasonably small compass which would be quite suitable for most courses in the subject elsewhere. No serious errors were noticed beyond the statement (p. 98) that no work is done in Joule's experiment because the gas rushes into a vacuum. This is a common error; the fact is that the change occurs in a rigid vessel and so external work cannot be done. The book is well printed and illustrated on good paper, the production being Indian, but the binding is not so good.

The Theory of Valency and the Structure of Chemical Compounds

By Prof. P. Rây. (Cooch-Behar Professorship Lectures for 1941.) Pp. vii+82. (Calcutta: Indian Association for the Cultivation of Science, 1946.) n.p.

THESE lectures deal with the development of the theory of valency from its origin to the latest quantum-mechanical views on the subject. The subject is discussed concisely, but the exposition is clear and interesting. Some of Prof. Rây's own work is dealt with, and there is a useful bibliography.

Wonder of Wings

A Book about Birds. By Nancy Price. Pp. 253+16 plates. (London: Victor Gollancz, Ltd., 1947.) 14*s*. net.

A PLEASANT book is this, a volume of chat, gossip and discussion concerning birds, bird matters and problems. It is a book that can be picked up and put down, and picked up again, to dip into here, there and anywhere, the reader each time finding something new, readable and interesting. Many of the chapters are dialogues between Miss Price and her neighbour, "the Birdman", their discussions ranging over a wide variety of bird topics, from how the gods punished the raven for its sins by turning it a sombre black, to legends concerning the wren, and the story of the willow pattern plate. The author is a little confused with regard to Capt. Knight's well-known eagle, "Mr. Ramshaw", which she refers to as a martial eagle. Capt. Knight had a martial eagle; but "Mr. Ramshaw", hero of many travels and adventures, was a golden eagle of Scottish origin.

FRANCES PITT

ADSORPTION AND HETEROGENEOUS CATALYSIS*

By Prof. ERIC K. RIDEAL, O.B.E., F.R.S.

We now recognize two forms of adsorption: that in which the dispersive forces alone are operative—the so-called van der Waals or physical adsorption—and adsorption in which an electron switch has taken place between adsorbent and adsorbate—chemi-sorption. It is important to obtain criteria for distinguishing between these two forms so that we can identify the type or types involved in any particular case of heterogeneous catalysis.

The literature concerning adsorption is very voluminous, and we may refer to Brunauer's recent volume on physical adsorption to get an idea of its magnitude and extent. Here we merely observe that if we are to obtain a complete picture of such adsorption, more attention will have to be paid to the forces operative with different and definite substrates. A commencement has already been made, but we require more systematic investigation of the adsorption of polarizable and non-polarizable adsorbents on substrates which are respectively iónic, covalent and metallic in lattice structure. One may cite as an example of the former the adsorption of the rare gases on one hand, and of iodine on the other, on crystalline potassium chloride, whereby the theoretical treatment can be examined in the light of experimental data. As an example of the latter, we may mention the experimental work on the adsorption of vapours at the surface of liquid mercury, which reveals the shortcomings of the various theoretical expressions which have been derived for such interactions with metallic surfaces.

Apart from the complications introduced by the fact that the adsorbing surface is scarcely ever uniform, it is by no means improbable that many cases of physical adsorption on what is believed to be a metallic substrate may well be taking place on the top of a chemi-sorbed monolayer such, for example, as hydrogen on tungsten, on which there is already a chemi-sorbed monolayer of gas such as tungsten oxide or tungsten hydride. The slow uptake of gas which results on the admission of a gas to a bulb containing finely divided reduced metal, or other solid, may be due to the formation of a chemi-sorbed layer on its surface, or to a process of solution and diffusion into the interior of the solid. The data derived from a study of the kinetics of such processes have been interpreted on a basis both of 'activated' adsorption and of 'activated' diffusion. It is clearly important to be able to distinguish between these two different processes, since either of them might prove to be the controlling reaction in a case of heterogeneous catalysis. Valuable information may be obtained by studying the processes on surfaces freshly prepared *in vacuo*. So far, tungsten wire and mirrors of other metals deposited by thermal evaporation have been employed.

Different physical methods are available for examining the surface properties of a wire or a mirror. Thus the accommodation coefficient for a gas, the heat change, the thermionic and photo-electric properties all provide information on the presence or absence and, indeed, on the structure also of chemi-sorbed monolayers.

Such experiments reveal the fact that many cases of slow uptake of gas, which had been attributed to the chemi-sorptive process, possessing a definite and large energy of activation, were in reality due to other causes; for example, solution or displacement of one surface layer by another, since the chemi-sorptive process proceeded on the clean metal surface without any appreciable energy of activation.

While there may be some doubt in particular cases as to the exact magnitude of the energy of activation involved, it is relatively small compared to the bond-strengths of the ordinary diatomic gases which undergo dissociation on chemi-sorption. The metal-electron substrate must act in a manner analogous to a free radical. That an electron switch has taken place during chemi-sorption is revealed by the strong dipole character of the chemi-sorbed complex; for example,

$$\overset{-}{\mathrm{W}}\,\mathrm{C}\overset{+}{\mathrm{S}} \text{ or } \overset{+}{\mathrm{W}}\,\overset{-}{\mathrm{O}},\ \overset{+}{\mathrm{W}}\,\overset{-}{\mathrm{H}}.$$

In several cases, for example, oxygen and ethylene, the reacting electron is probably the π-electron of the adsorbate; whereas many catalytic metals, for example, those in the transition group, have a narrow *d*-band overlapped by a broad *s*-band of electron-levels, and it is possibly an electron-level in this band which is involved. While a number of experiments have been carried out to determine the thickness of metal required for the emergence of 'metallic' characteristics, the great experimental difficulties involved in maintaining the substrate, in the effects of surface tension, in formation and preservation of a thin continuum in lattice form, have so far hindered progress in this direction. It is possible that further advances in our knowledge of the nature of the chemi-sorbed complex may come through physical examination of such systems, for example, the determination of specific heats of surface films, of the dielectric constant and para- or dia-magnetic susceptibilities. Experimentally, such investigations are proving to be within the compass of modern technique.

One of the most important problems connected with adsorptive phenomena is that concerning surface mobility. Under what conditions are adsorbed layers, held by dispersive forces and chemi-adsorbed layers respectively, mobile over the surface? The surface field is an undulating periodic one, and movement from one site to another may involve evaporation and recondensation, or movement over a potential hill. The adatom or adion may be raised into a migratory level. Here it may be free to move all over the surface, or may be limited to flight in one line only. It may move only into the next trough, or have a relatively long range of flight. We can develop equations to satisfy each of these conditions, but the experimental evidence so far is too inexact and too scanty to make any decision.

In the case of the alkali metals on tungsten, the data favour the view that the ion in the migratory level is restricted to a linear path and can traverse several tungsten atoms before terminating its flight. The growth of crystals from the vapour phase and the migration of organic molecules and metallic atoms over glass surfaces provide further evidence for lateral mobility. Such evidence as is available at present suggests that lateral mobility of physically adsorbed molecules, but not of the chemi-sorbed species, can occur within the range of temperature at which the catalytic reactions occur. We cannot, however, eliminate the possibility of some mobility even in the chemi-sorbed species.

---

* Substance of a course of three lectures delivered at the Royal Institution on February 12, 19 and 26.

Several hypotheses concerning surface catalysis involve the concept of two-dimensional gas reactions. The experimental evidence available suggests that in surface reactions chemi-sorbed reactants, and not physically adsorbed reactants, are involved; thus the question of mobility becomes one of great importance. Apart from the fact that this mobility for the chemi-sorbed species appears to be non-existent or extremely limited, we must note that the adatoms have dipole moments, and as a result strong repulsive fields exist between them. It is interesting to compare this repulsive or spreading pressure of a film of adatoms where the pressure is due to a free two-dimensional gas, that is, one which obeys the formal relationship

$$F = \sigma KT,$$

where σ is the surface density of adatoms, with the pressure due to a free two-dimensional array of dipoles, that is,

$$F^1 = 4{\cdot}51\, \mu^2\, \sigma^{5/2},$$

where μ is the dipole moment. At values of $\sigma = 0{\cdot}8 \times 10^{14}/\text{cm.}^2$ and $4{\cdot}6 \times 10^{14}/\text{cm.}^2$, the values of F and F^1 are for formic acid on mercury 14 and 52 dynes/cm. for F, and for potassium on tungsten 26·0 and 307 dynes/cm. for F^1 respectively. The value of the dipole moment μ likewise changes as we alter the surface density of the film, due to mutual interaction.

Examination of the heats of adsorption gives us some indication as to the extent of mutual interaction which is repulsive in the chemi-sorbed layer, as well as on the mobility of the film. It is interesting to note that, in the physically adsorbed layer, below the critical temperatures attractive forces appear to predominate; for example, in the condensation of metallic and other vapours on glass.

In the chemi-sorption of a diatomic gas such as hydrogen on the surface of a metallic lattice, the molecule undergoes dissociation to form a pair of metallic hydride molecules. If the film be immobile during the process of filling up the lattice, some eight per cent of the lattice points will be left isolated as singlets. These singlets may play an important part in heterogeneous catalysis. Two of the simplest cases of heterogeneous catalysis are the ortho-para conversion of hydrogen or deuterium and the exchange reaction between hydrogen and deuterium at the surface of non-paramagnetic metals. The reactions proceed smoothly at quite low temperatures with small but definite energies of activation. In the cases which have been examined, the metal is covered with a chemi-sorbed layer of hydride broken only by the gaps already referred to. The formal kinetics of the reaction and reference to the corresponding homogeneous reactions preclude the possibility of the reaction proceeding by a two-dimensional bimolecular gas reaction in a mobile physically adsorbed phase on the top of the chemi-sorbed atomic or hydride layer. One of the current views is that the reaction proceeds by interaction of two neighbouring adsorbed hydrogen adatoms with subsequent evaporation of the newly formed molecule. In view of the repulsive forces which we have shown to be operative and the great heat of adsorption even in a closely packed film, it is clear that many difficulties have still to be overcome before this hypothesis as to the mode of action can be freely accepted.

An alternative proposal involving an interaction between a physically adsorbed molecule situated over one of the vacant sites, and a neighbouring chemi-sorbed adatom to form a transition complex, presents us with a mechanism involving exchange of valence forces rather than rupture of any primary bonds, and goes far to overcome the difficulties associated with the other two proposed mechanisms. Many of the heterogeneous catalytic reactions can be readily interpreted by means of such a mode of action, but experimental re-examination of some of the catalytic exchange reactions is necessary before an unequivocable decision is possible.

The mechanism proposed, it will be seen, involves what is, in fact, the half-hydrogenated state which in the catalytic chemistry of the hydrocarbons has proved such a useful concept. The hypothesis of vacant sites inaccessible to particular reactants suggests their accessibility to other species, and provides us with an explanation of the broken linear character of the curves connecting poisoning with catalytic activity, an explanation alternative to a series of patches of different activity. Dissociation in chemi-sorption involves not only an electron switch, but also the problem of interatomic spacing; the relation of both these factors to the energetics of surface action provides yet another field of inquiry as yet almost unexplored. Provisional theoretical examination of the effects of surface spacing on the activation energy have not taken the electron distribution in the substrate into consideration; while attempts to evaluate energies of activation by examination of metals which form a continuous series of solid solutions and thus provide a gradual change in the mean lattice spacing, require a more detailed examination of the composition of the Gibbs surface layer and its dimensions before we can draw justifiable conclusions.

THE MAIN GEOMAGNETIC FIELD

THE main geomagnetic field and its secular variation were the subject of a Geophysical Discussion held at the Royal Astronomical Society on February 27. The largely attended meeting, at which the Astronomer Royal was chairman, was addressed by Dr. E. C. Bullard, of the Department of Geodesy and Geophysics, Cambridge (who is shortly to take up the post of head of the Department of Physics in the University of Toronto), Dr. J. McG. Bruckshaw, in charge of the sub-department of applied geophysics at the Imperial College of Science and Technology, London, Mr. D. W. Bishopp, director of the Geological Survey of Eire, and Mr. S. K. Runcorn, of the Physics Department in the University of Manchester.

Dr. Bullard outlined a new theory of the secular magnetic variation. He first recalled the main character of this variation, as exemplified by the longest series of observations, for London, which suggests a cycle of change of magnetic direction, of which about three-quarters has been completed in four centuries. Other places, however, show variations that suggest shorter periods. The accumulated data discredit the hypothesis, formerly advanced, that these changes are due to a rotation of the geomagnetic axis about the geographical axis. Bartels has shown that the secular variation is regional in character, differing from the main field itself, which is planetary. The secular variation studies made by Fleming and Fisk, and more recently by Vestine and his collaborators, at the Department of Terrestrial Magnetism of the Carnegie Institution of Washington, show that at any one epoch the secular variation is most active in certain limited regions, but that such activity may die away in the course of a few decades, new centres of activity appearing elsewhere. These characteristics are substantiated by the occasional rather rapid changes of rate and direction of the secular variation at magnetic observatories, where the field is most accurately determined.

This time scale of the secular magnetic variation is one of its most remarkable features. Cycles of change of a few centuries in duration, and still more the observed changes during a few decades, are very rapid for a phenomenon that undoubtedly originates within the body of the earth; ordinary geological changes require millennia or even millions of years for their evolution. The rapidity of the secular magnetic variation excludes any theory based on motions or thermal changes in the solid outer portion of the earth. A deeper source must be sought, in the liquid core, the existence of which is inferred from the failure of transverse seismic waves to pass through or near the earth's centre.

Dr. Bullard discussed particularly the rapid secular variation in and near South Africa during recent decades. The isoporic charts, which show the lines of equal rate of secular change, are somewhat complicated; a clearer conception of the variation over this region is obtained by plotting the rate-of-change vectors for the horizontal component, and indicating beside them the positive or negative rate of change of the vertical component. It is still better to draw the (inclined) rate-of-change vectors of the secular variation (vertical as well as horizontal) in the median vertical plane through the region, in the direction of the horizontal change—roughly the north-west to south-east direction. Taking the region to extend over 25° or 30° in this direction (over which range the curvature of the earth is, of course, important), the vectors at the north-west end slope upward, those at the south-east end slope downward, while intermediately they are nearly horizontal.

Dr. Bullard finds that these vectors for surface points correspond approximately, in magnitude and direction, to the field of a nearly horizontal magnetic dipole situated near the surface of the earth's liquid core, below the centre of the region. The estimated moment of the dipole for the change in one year is $3 \cdot 5 \times 10^{22}$ gauss (Γ) cm.^{3}. If the change continued for a century, the equivalent dipole moment would be $3 \cdot 5 \times 10^{24}$ Γ cm.^{3}—about 4 per cent of the moment (8×10^{25}) of the earth's main field. The dipole of the secular variation may not attain this value; it may die away again within a century from the commencement of secular activity in this region, a possibility to be confirmed or negatived only by future observation in this region.

The origin of the secularly evolving magnetic dipole is attributed by Dr. Bullard to an electric current circuit, flowing in the mass of an eddy near the surface of the core; the current is supposed to be produced by electromagnetic induction by the circulatory motion in the eddy, in the presence of the permanent magnetic field. Dr. Bullard is inclined to infer that at that depth the magnetic vector is more nearly vertical than at the surface point directly overhead. He has considered, to a degree of detail not possible to reproduce here, various numerical values pertaining to the dipole mechanism; a few of his illustrative estimates may be cited. If the radius of the eddy is 300 km., the electric current intensity must be of the order 4×10^{-5} amp./cm.^{2}, the total current being about 3×10^{11} amp. The time of circulation in the eddy may be of the order 0·3 year. Under the conditions supposed to prevail at the surface of the core, where the electrical conductivity can be roughly estimated, these would be a possible set of values. The Reynolds number is estimated as 5×10^{11}; Dr. Bullard suggests that the eddy would disappear by break-up rather than by frictional decay. He considers that developing dipole fields of eddies more than a few hundred kilometres below the surface of the core would be shielded by currents induced in the upper part of the core, so that the observed secular variation at the earth's surface will be due to the uppermost core eddies.

This fascinating theoretical discussion was followed by Dr. J. M. Bruckshaw's account of some observations of great theoretical interest on the magnetic anomalies associated with the main tholeiite dykes of the north of England, a system of volcanic dykes extending from the Isle of Mull to the north-east coast of England. This work was done in conjunction with E. I. Robertson, a New Zealand research student, aided by a team of student observers. The dykes are tertiary igneous intrusions, perhaps fifty million years old; they are nearly vertical, and only 10–25 yards thick. Since their formation they have remained undistorted by any major earth movements, though displaced slightly here and there by local faults.

The vertical magnetic intensity (V) was measured at points along sixty-five traverses across the dyke; pronounced anomalies were observed, of amounts up to 2,500 γ. Each traverse gave a graph of the variations of V. Rock specimens were also taken, their orientations *in situ* being carefully noted; laboratory measurements of their susceptibility and permanent intensity of magnetization (I) thus enabled the magnitude and direction of the resultant I for the dykes to be determined. The observed anomalies in V agree well with those calculated from the size, form, position and magnetization of the dyke at various places along it. The outstanding feature disclosed by the investigation is that the dyke is magnetized in a direction nearly opposite to that of the present geomagnetic field in the locality.

Observations in volcanic regions to-day show that the magnetic lavas that well upwards as a molten magma become magnetized by induction in the earth's field as they cool through the Curie point. Mercanton, Thellier and others have shown that in many cases such rocks have great magnetic retentivity, and most of the rock specimens collected in this investigation show the same property, though in a few cases their magnetization declined appreciably within a few months. The simple interpretation of the observed data is that the earth's field in this region fifty million years ago was opposite in direction to that which now exists there. The poor retentivity of a minority of the rock specimens may explain the few cases in which the magnetization has the present direction of the field. In general, the observed anomalous I is two to eight times as intense as the present field would induce.

Such anomalous magnetization has previously been observed in Germany, in the Arctic (by Mercanton), in New Zealand, and (perhaps the most striking case) in the Pilansberg dykes in South Africa, which are palæozoic, perhaps two hundred to five hundred million years old. Mr. D. W. Bishopp, in his account of a recent survey of the vertical force (V) over Eire (from which two magnetic maps, not yet published, have been prepared), added further examples, also of tertiary intrusions, showing the 'wrong' sign of magnetization.

The Pilansberg dykes are not too far from the equator to exclude the possibility of explanation, in their case, by the hypothesis that in the course of the secular variation the *magnetic* equator has passed across this region, corresponding to a reversal of the local value of V. But this explanation could not be applied to regions so far north as the Border or as Eire. It is difficult also to see how Dr. Bullard's explanation of the secular variation could account for a local reversal of the field. Geologists present at the discussion remarked that in tertiary times the molten layers seem to have come unusually near the surface; but it is not clear how this could help to explain a reversal of the field. A very extensive continental drift carrying great land masses across the equator is another possible but unattractive hypothesis that would obviate the conclusion that the earth's field as a whole was once of opposite polarity. This conclusion would, of course, be quite inconsistent with any 'fundamental' theory associating magnetization with rotation in the case of large rotating masses, such as Prof. P. M. S. Blackett has advocated.

The fourth contribution to the discussion, by Mr. S. K. Runcorn, bore on this hypothesis. When Prof. Blackett in May last read his paper on the 'fundamental' theory of magnetization by rotation, Dr. Bullard pointed out that the variation of the magnetic intensity with depth within the earth should provide a crucial test between such a theory, and the usual 'core' theories which assign the source of the earth's field to some cause within an inner core of the earth. Any core theory, which regards the overlying portion of the earth as non-magnetic, implies that V and H both vary as $1/r^3$ at distance r from the earth's centre, outside the core. On the fundamental theory, in which every element of mass contributes in some way to the field, the intensity might be expected to decrease downwards. The depth-variation of intensity on the fundamental theory, for different distributions of density within the earth, has since been calculated by Mr. Runcorn and also by Chapman; it appears that near the surface V varies as $1/r^3$ whatever the density distribution (assumed spherically symmetrical), so that measurements of the depth variation of V cannot distinguish between the fundamental and the core theories. The 'fundamental' depth-variation of H, however, is a downward decrease, depending on the density distribution; this therefore, as Dr. Bullard suggested, offers a possibility of deciding between the two theories.

Observations of H in South Africa at an effective depth of 4,800 ft. in a Witwatersrand mine have recently been reported in *Nature* (**160**, 746; 1947); they show a decrease, favouring the fundamental theory; but there is great need of further measurements in regions less disturbed magnetically than the Witwatersrand. Mr. Runcorn gave a preliminary account of such measures in a coal-mine at Leigh, in Lancashire, in a region apparently devoid of any appreciable magnetic anomalies. He, Mr. A. C. Benson and Mr. S. Goldsack, of the University of Manchester, have measured both V and H at a depth of 4,000 ft., in a disused working, well removed from any iron or steel mining structures. Comparison with V and H measured at the surface show the expected downward increase of V, and a *decrease* in H; $\Delta H = -45\gamma$ approximately, as against $\Delta H = +13\gamma$ as expected on the core theory. An intensity of magnetization of $0\cdot08\ \Gamma/\text{cm.}^2$ in the top layer 4,000 ft. deep would be needed to account for this value of ΔH, and this layer is certainly not so magnetized (and if it were, V would also be affected by it).

Prof. Blackett pointed out the great importance of such observations, which if verified would indicate a hitherto unrecognized property of matter which is not magnetic in the ordinary sense of the word. Prof. T. G. Cowling remarked on the indefiniteness of the concept of angular momentum in connexion with fundamental theories of magnetization by rotation, and Prof. Blackett agreed that such theories must at present be regarded only as provisional.

The whole discussion showed that this relatively old science of geomagnetism remains lively and vigorous, and the new contributions made by Prof. Blackett and Dr. Bullard will undoubtedly provide much stimulus to further observations and their interpretation.

S. CHAPMAN

STRUCTURE OF AN ANIMAL VIRUS

By Dr. I. M. DAWSON and Dr. A. S. McFARLANE
National Institute for Medical Research, Hampstead, London

BECAUSE of their crystallinity, a great deal is known about the ultimate chemical structure of the plant viruses, whereas little or no corresponding information is available for the animal viruses. Efforts to obtain X-ray diffraction patterns have not been successful, and attention has been turned in recent years towards the electron microscope as the tool most likely to solve the problem. For obvious reasons attention in the first instance has been directed to the larger animal viruses, but with the exceptions of nuclei-like bodies in the Rickettsiæ[1] and less definite internal bodies in the pox group[2,3], this technique has also proved disappointing. It is clear on the practical side that the size and density of the infective particles is such that 100-kV. electrons can only just penetrate them, and any internal differences in electron density which may exist must be of a low order—probably less than 20 per cent.

In the pox group of viruses, outlines of a central body were first seen by Green *et al.*[2], with vaguer indications of the presence of four satellite bodies occupying the corners of the brick-shaped particles. The viruses of this group are all purified by differential centrifugation from dilute buffer suspensions, and it is a common experience[4,5], especially with vaccinia, to find structureless material present in the background of the electron micrographs—sometimes linking neighbouring particles as if by gelatinous bridges—which persists after repeated differential centrifuga-

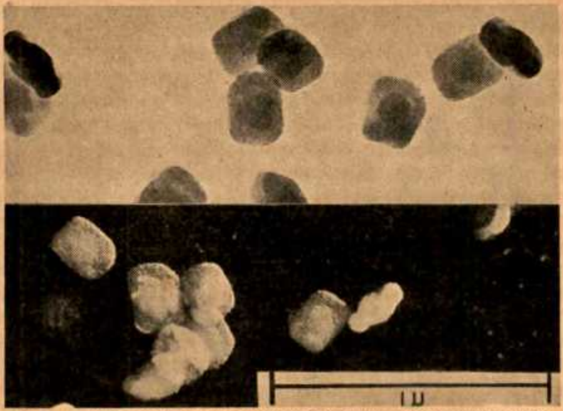

Fig. 1. VACCINIA VIRUS PURIFIED BY SALT FLOCCULATION AND FIXED WITH OSMIC ACID. ABOVE, UNSHADOWED; BELOW, LIGHTLY SHADOWED WITH GOLD TO REVEAL SURFACE STRUCTURE. SCALE INDICATES 1μ

tion. Increase of salt concentration leads to flocculation of the virus, which with vaccinia in molar sodium chloride in the cold is complete in one to three days. As an indication that some purification has been effected, the flocculum which settles out is free of the slight but tenacious pigmentation of the original virus. The supernatant is still faintly turbid and contains in particulate and soluble forms 30–40 per cent of the original virus, with roughly proportionate amounts of nitrogen, phosphorus and desoxyribonucleic acid. After repeated washing with distilled water to remove the last trace of salt, the flocculated virus can be quantitatively redispersed into dilute buffer with the aid of sonic or ultrasonic vibrations[6]. The infectivity is not seriously reduced by the treatment, the virus having been passed through several host animals with exhaustive sodium chloride extraction and sonic resuspension at each passage.

Electron micrographs (Figs. 1, 3) show a complete absence of background material in the salt-extracted virus. Occasionally one or two particles are visible standing on edge (Fig. 1) and revealing a thickening at the centre and smaller ones at the corners. Consideration of the blackening caused by one particle overlapping another in conjunction with the shape of the particles suggests that the dark areas seen in the transmission pictures at the centres and corners of the bodies can be explained sufficiently by the geometry of the particles without invoking internal differences in scattering capacity. The relative sharpness of the edges of the central areas, however, is difficult to reconcile with this view.

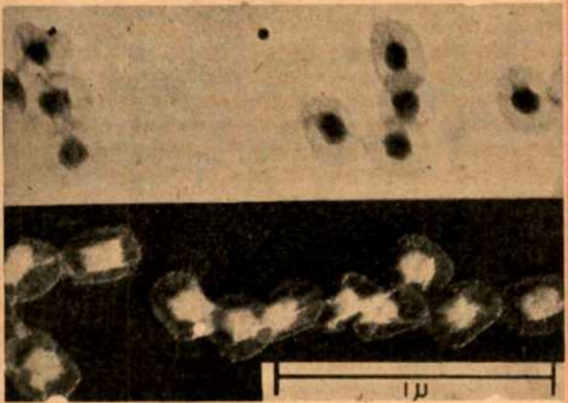

Fig. 2. SAME AS FIG. 1, BUT AFTER PEPTIC DIGESTION OF THE VIRUS

Digestion with pepsin is known to be a useful adjunct to alkali in removing the nucleic acid from vaccinia[7] and we have, therefore, made an electron microscopical investigation of the action of this enzyme. Incubation of the virus at pH 3·0 and 37° C. for several hours causes no visible alteration in it; but in the presence of a few micrograms of crystalline pepsin three-quarters of the virus substance goes into solution in half an hour. Micrographs of the residual particles (Fig. 2) show that the central body is certainly not an artefact. No traces of satellite bodies are seen, however, indicating that the dark areas in the corners are to be identified with local thickenings of the virus substance, or with intracellular particles which, unlike the central ones, are hydrolysable with pepsin.

The action of pepsin is complete in half an hour, practically all the phosphorus and desoxyribo-nucleic acid of the salt-extracted virus being retained in the residue. Incubation of this with desoxyribo-nuclease (kindly supplied by Dr. M. Kunitz, Rockefeller Institute, Princeton, N.J.) at pH 7·5 for 1 hr. results in liberation of the nucleic acid in soluble form. This treatment does not seriously alter the architecture of the residual cell, but some loss of density occurs in the central body. These observations show that this body has some, at least, of the characteristics ordinarily attributed to a nucleus, and seem to justify the use of this term for it. It is, of course, of an altogether lower order of size (c. 90 mμ diameter) than anything hitherto designated as such, and the term is used without any implication that this virus nucleus is capable of subdivision in any genetic sense.

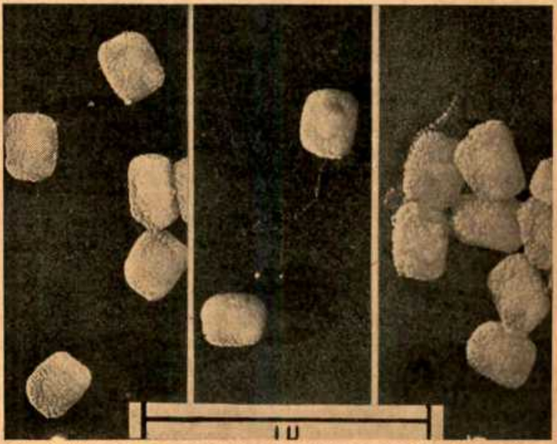

Fig. 3. SAME AS FIG. 1, BUT MORE HEAVILY SHADOWED WITH GOLD

Folds are clearly visible in the perinuclear part of the pepsin-digested virus (Fig. 2) and also in ghosts of the virus obtained by the action of sodium hydroxide[2]. These are similar to the folds seen in erythrocyte ghosts[8] and seem to argue convincingly in favour of the presence of a thin limiting membrane. The resolution of the electron microscope is not sufficient to identify a pattern in the substance of the membrane with any certainty. Gold-shadowed pictures (Figs. 1, 3) of the salt-extracted virus, however, show a granularity of a higher order than that seen in the background and which at some places on the virus surface is remarkably regular in arrangement—presumably reflecting a close packing of protein macromolecules. We have observed occasionally in several pictures (Fig. 3) chains of apparently similar 'macromolecules' which may have been stripped accidentally from virus particles, but without any signs of correspondingly deficient areas or strips on virus bodies. These in conjunction with photographic density considerations suggest that the granularity is not restricted to the surface but has a bulk distribution throughout the perinuclear space.

Since the envelopes collapse after removal of the protein within (Fig. 2), they cannot alone be responsible for the characteristic cuboidal shape of the virus. Something more is necessary, and we may consider in this connexion two suggestions which have been put forward[9] to explain shape in larger cells, and in particular the biconcave shape of the mammalian erythrocyte. On one hand, a submicroscopic network or reticulum is envisaged into which the molecules fit and upon which they confer a rigidity; and on the other, intermolecular attractions of the kind which hold a protein crystal together are invoked. The fundamental difference between the two views is the chemical one that in one case only protein removable by hæmolysis (or peptic hydrolysis in the case of the virus) is present, while in the other this protein is interspersed with resistant stroma protein. Practical differentiation by chemical or physical means is extremely difficult, and at least in the case of the red cell has not been satisfactorily achieved. Ponder has to conclude a recent paper[10] with the statement: "Changes in a membrane alone seem inadequate to account for the varied phenomena observed in connexion with red cell behaviour, the explanation of which appears to require a more detailed knowledge of the molecular architecture of the cell interior". At the same time he is able in this paper to provide experimental support for Teitel-Barnard's demonstration[11] of para-crystallinity in the red cell. He finds local areas of birefringence in rat red cells preserved in citrate, and this observation may be of interest in relation to the patchy distribution of particle regularity which we observe in the virus. It suggests that our first impression that a partial disorientation occurs on drying may be wrong, and, in fact, the cytoplasm of the native virus contains protein phases of different degrees of orderliness, from the loose molecular arrangement which holds in protein gels up to the perfect regularity of a protein crystal.

With regard to the alternative stroma hypothesis, evidence is available, mainly from studies of form birefringence, for the existence of submicroscopic fibrils in the cytoplasm of cells, for example, of retinal rods[12] and egg cells[13]. Two pieces of evidence, neither of them conclusive, favour the existence of a fibrillar arrangement in vaccinia. It is noticeable after peptic hydrolysis that the nuclei are almost always centrally placed in the cell as if held there by an invisible net. The second point is derived from considerations of the shrinkage which occurs on drying. Virus particles from which the water has been sublimed at −70° C. have major dimensions 250 mμ by 200 mμ with ± 5 per cent individual variations. The mean thickness as measured at the periphery from profile views and shadow lengths is estimated to be 110 mμ. Drying at room temperature causes a reduction in the mean thickness to one half without giving rise to any appreciable alteration in the other two dimensions. Treatment with osmic acid, on the other hand, followed by drying at room temperature, causes a uniform shrinkage of 20 per cent in all dimensions. The latter behaviour is explained by protein fixation on any hypothesis of particle architecture; but the conception of a supporting network helps to explain the manner of subsidence of the particle when dried above zero without fixation. Contact with the supporting surface prevents shrinkage in the horizontal plane, while a concertina-like contraction of the network takes place in the vertical plane.

Whereas the facts outlined here do not provide a complete picture of the structure of vaccinia, they establish that it is definitely more complex than that of the fully crystalline plant viruses. On other grounds, Anderson[14] is inclined to identify this virus structurally with the bacteria. A major difficulty which we have in accepting this is that so little is known about the internal organisation of bacteria in spite of their much larger size. It is doubtful, for example, whether the controversy surrounding the existence of nuclei in the accepted cytological sense in bacteria has ever been livelier than at present[15], and curious new structures are coming to light as a result of phage studies[16]. In a preliminary way we have subjected a bacterium (*Proteus vulgaris*) to the action of molar sodium chloride followed by pepsin, and observed that the effects are different both qualitatively and quantitatively from those encountered with vaccinia.

NEW FELLOWS OF THE ROYAL SOCIETY

At the meeting of the Royal Society on March 18, the following were elected to fellowship:

Dr. T. E. Allibone, director of the Research Laboratories of Associated Electrical Industries, Aldermaston, Berks, distinguished for his contributions to the application of high-voltage phenomena.

Dr. F. P. Bowden, lecturer in physical chemistry, University of Cambridge, distinguished for his contributions to the study of friction and lubrication.

H. Constant, deputy director (research), National Gas Turbine Establishment, distinguished for his studies in the applications of thermodynamics and aerodynamics to aircraft engines.

Dr. S. F. Dorey, chief surveyor, Lloyd's Register of Shipping, distinguished for his contributions to marine engineering.

E. H. Farmer, assistant director and senior organic chemist of the British Rubber Producers' Research Association, Welwyn Garden City, distinguished for his experimental studies of complex unsaturated hydrocarbons and related natural products.

Prof. O. R. Frisch, Jacksonian professor of physics in the Cavendish Laboratory, Cambridge, distinguished for his researches on fission processes in nuclear physics.

Sir John Fryer, secretary of the Agricultural Research Council, distinguished for his services to agricultural science and his contributions to applied entomology.

Prof. T. M. Harris, professor of botany in the University of Reading, distinguished for his researches in palæobotany.

Prof. W. H. Heitler, senior professor in the School of Theoretical Physics, Institute for Advanced Studies, Dublin, distinguished for his contributions to theoretical physics.

A. L. Hodgkin, assistant director of research in physiology, University of Cambridge, distinguished for his researches on the nature of nervous conduction.

Dr. G. M. Lees, chief geologist to the Anglo-Iranian Oil Company, distinguished for his contributions to stratigraphical and structural geology, particularly in relation to oilfields.

Prof. R. A. McCance, professor of experimental medicine, University of Cambridge, distinguished for his contributions to metabolic studies of human beings.

Dr. K. Mahler, senior lecturer in mathematics in the University of Manchester, distinguished for his researches in the theory of numbers.

Dr. Sidnie M. Manton, lecturer at King's College, London, distinguished for her work on the Crustacea and other invertebrates.

Dr. Dorothy M. Needham, of the School of Biochemistry, University of Cambridge, distinguished for her researches on the biochemistry of muscle.

Prof. J. H. Orton, professor of zoology, University of Liverpool, distinguished for his investigations in marine biology.

Sir Leonard Parsons, emeritus professor of diseases of children, University of Birmingham, distinguished for his studies on child health and the wasting disorders of children.

Dr. Stanley Peat, reader in organic chemistry, University of Birmingham, distinguished for his contributions to the constitution and synthesis of carbohydrates.

Prof. G. W. Robinson, professor of agricultural chemistry, University College of North Wales, Bangor, distinguished for his contributions to the study of soils.

Dr. W. A. H. Rushton, university lecturer in physiology, Cambridge, distinguished for his researches on the effect of electrical stimuli on muscles and nerves.

J. W. Ryde, senior physicist in the Research Laboratories of the General Electric Company, Wembley, distinguished for his contributions to pure and applied physics.

G. R. S. Snow, fellow of Magdalen College, Oxford, distinguished for his work on plant hormones and growth.

Dr. E. W. R. Steacie, director, Division of Chemistry, National Research Council, Canada, distinguished for his researches on gaseous chemical reactions.

Dr. J. A. Todd, lecturer in mathematics, University of Cambridge, distinguished for his researches into the geometry of figures.

Dr. F. Yates, chief statistician, Rothamsted Experimental Station, distinguished for his contributions to the statistical analysis of agricultural problems.

NEWS and VIEWS

Mathematics at Leeds: Prof. S. Brodetsky

THE retirement has been announced of Prof. S. Brodetsky, professor of applied mathematics and head of the Department of Mathematics in the University of Leeds. It must be but rarely that the career of any distinguished scientific man borders on the romantic, but the career of Prof. Selig Brodetsky certainly furnishes one of these rare cases. He was born sixty years ago of orthodox Jewish parents at Olviopol, a village in Russia near Odessa. The prevalence of pogroms against the Jews in the Russia of those days decided the father to seek an asylum for himself and his family in England. He left Russia by himself first of all, and after he had established a means of livelihood in London, he sent for his wife and four children to join him. It was an adventurous journey across Europe for a young woman with four young children, and Brodetsky has frequently told how, as a child of four years of age, he clung to his mother's hand while crossing a frontier, while she pushed a corner of her shawl into the mouth of his little sister in arms to prevent her crying and so attracting the attention of the frontier guards. The number in the family increased steadily in London and the *res angusta domi* was never far absent from their home. But Brodetsky's father was a man mighty in the Scriptures and particularly well-versed in the Talmudic writings, so that young Selig was reared in a home pervaded with traditional Jewish culture and an intellectual outlook although in a restricted field. The result was that several of the children overcame all obstacles and entered universities.

Brodetsky was educated at the Jews' Free School and at the Central Foundation School, London. He entered Trinity College, Cambridge, and was Senior Wrangler in 1908, a feat on the part of a Russian-born boy which evoked much interest and astonishment at the time. After five years as a lecturer in the University of Bristol he joined the mathematical staff at the University of Leeds and became professor of applied mathematics there in 1924. Prof. Brodetsky's twin interests through life have been applied mathematics, particularly aerodynamics, and the cause of the Jewish people. He has been an indefatigable worker for Zionism. As a university teacher, he was a brilliant expositor of mathematical subjects, both on the academic platform of the university and to lay bodies outside its walls. He carried out much research work and wrote several mathematical treatises. Brodetsky is a man of great bodily vigour and unquenchable vitality. His knowledge of Europe and foreign affairs generally made him invaluable in shaping university policy both inside Leeds and more generally in consultation with his colleagues in other centres of learning. His fruitful activities in university life will be seriously missed.

Prof. H. S. Ruse

Prof. H. S. Ruse, who has succeeded Prof. S. Brodetsky as head of the Department of Mathematics in the University of Leeds, was an undergraduate at Jesus College, Oxford, during 1924–27. After spending nearly ten years as a lecturer on the mathematical staff at the University of Edinburgh, he became professor at University College, Southampton, in 1937 and he remained there until he went to Leeds in 1946 as successor to Prof. W. P. Milne on his retirement from the chair of mathematics. In 1931 Ruse spent a period in Rome working with the late Prof. Levi-Cività, and in 1933–34 he was on leave of absence from Edinburgh working with Prof. Oswald Veblen at the University of Princeton. Prof. Ruse's main interest is relativity and tensor analysis and he has published a great many original papers in this field in the leading mathematical journals.

In the University of Leeds with its large number of applied science departments, the Department of Mathematics occupies a focal position, and it has a great contribution to make to the work and development of the technological departments. There is a long tradition in the University of a close and cordial co-operation between the Department of Mathematics and the applied sciences, and *ad hoc* courses in mathematics suitable for the individual needs of the technological departments and the Medical School have, so far as the size of the mathematical staff permitted, for long been provided. Prof. Ruse is in complete sympathy with this liaison between the pure and applied sciences, and intends to develop it still further. The Department of Statistics under the readership of Dr. B. L. Welch is within the Department of Mathematics, and this fruitful relationship is already being felt throughout the University in the development of statistical methods. There is a movement afoot for co-operation being established between the universities of northern England in the systematic pursuit of mathematical research, and this activity also has Prof. Ruse's warm support. It need scarcely be said that, in addition to the above affiliations, the cultivation of the science of mathematics for its own sake will be vigorously pressed forward under the leadership of the new head of the Department of Mathematics in the University of Leeds.

Prof. T. G. Cowling, F.R.S.

Prof. T. G. Cowling, who succeeds Prof. Brodetsky in the chair of applied mathematics at the University of Leeds, received his mathematical university training at Brasenose College, Oxford, and in 1931 was awarded the D.Phil. degree for a thesis dealing with the magnetic field of the sun and the radiative equilibrium of a spherical star. Afterwards he held lectureships in the mathematical departments at the Imperial College of Science and Technology, London, the University Colleges at Swansea and Dundee, and the University of Manchester, before being appointed to the chair of mathematics at University College, Bangor, in 1945. In 1947 he was elected a fellow of the Royal Society. He has written a large number of original papers on difficult problems of mathematical astrophysics, the kinetic theory of gases, the physics of the lower atmosphere and also of the ionosphere, and the magnetism of the earth, the sun and sunspots. His principal astrophysical papers deal with the stability of stellar models, the point source model of a star, convective equilibrium in stellar interiors, and the density distribution within stars as deduced from the motion of the apsidal line in close binary stars. He is also joint author with Prof. S. Chapman of the treatise "The Mathematical Theory of Non-Uniform Gases", and of a memoir on gaseous diffusion in a rare gas mixture. In this field one of his most important papers treats the problem of the electrical conductivity of an ionized gas in the presence of a transverse magnetic field. His work is characterized by great critical insight combined with constructive power.

University Representation in the House of Commons

When the Representation of the People Bill now before Parliament (see *Nature*, February 21, p. 259) came up for consideration on March 16 by the House of Commons in committee, Mr. O. Peake, member for Leeds, N., moved an amendment which was one of a series designed, he said, in accordance with the words of the unanimous recommendation of the Speaker's Conference, to maintain university representation and methods of election, and to ensure that registration of university graduates should in future be automatic and free. Some of the grounds for the retention of the university vote were set out in the article referred to above, and the support they obtained, not only from university representatives but also from other members of various shades of political opinion, showed that a case could well be sustained. The Government's spokesmen, however, Mr. Herbert Morrison and Mr. Chuter Ede, confined themselves practically to two points, namely, that the Speaker's Conference recommendation, having been made during a previous Parliament, was not binding on the present Government, and that the principle of plural voting was fundamentally wrong and "not in accord with a properly conceived democracy". Mr. Ede referred to the measure as one designed to redress electoral anomalies resulting from the Act of 1918 ; he said he had never believed in university representation, which he described as the last of the fancy franchises. The amendment was negatived by 328 votes to 198, a majority of 130.

Institute of Metals : Past and Future

The new president of the Institute of Metals, who took office on March 17 is Sir Arthur Smout, a director of Imperial Chemical Industries, Ltd., with special responsibility for the Company's metal and ammunition interests. A member of council of the University of Birmingham, and during 1942–45 director-general of ammunition production at the Ministry of Supply, he has had a life-long experience of the non-ferrous metal industries.

As this was the fortieth annual general meeting of the Institute, Sir Arthur, after paying a well-deserved tribute to his predecessor, Colonel P. G. J. Gueterbock, devoted the first part of his presidential address to its early history. The germ of the idea of such an Institute originated with a young engineer, W. H. A. Robertson—who was present at this meeting—in a letter in *Engineering*. A preliminary meeting held in Manchester in March 1908 was adjourned to London in June of that year, when the decision to go ahead with the plan was taken. This delay proved all to the good, as otherwise the trivial and clumsy title of "Copper and Brass Institute" might have been accepted. The fear of these pioneers that the Institute might fail through the disinclination of manufacturers to allow their technical staffs to present papers or take part in the discussions has fortunately proved groundless, and possibly one of the greatest services that the Institute has rendered to the industry is the breaking down of such prejudice and by providing a bridge across which scientific men and practical men can come into contact. The work of Shaw Scott, the first secretary and editor, received from the new president, who is in a position personally to appreciate his work, the fullest and most well-deserved praise. To Shaw Scott's guidance and devotion the Institute owes much. Among the papers read at the opening meeting in Birmingham in November 1908, Echavarri spoke of aluminium and its uses, and referred to the "enormous" demand for aluminium in 1906 and 1907 when the world production was 15,000 and 23,600 tons respectively; these figures are interesting in comparison with that of 1,890,000 tons a year at the peak of production during the Second World War.

The concluding part of the address was devoted to the future. As one concerned with both the metallurgical and the chemical industries, Sir Arthur contrasted the essentially continuous processes characteristic of the chemical industry with the 'batch' process normal in non-ferrous metal production. "To any industrial metallurgist laying down a new plant, I would commend the technical approach of the industrial chemist as worthy of close consideration." This represents the crux of the plea made for the reduction or, if possible, complete elimination of 'idle time'. Coming from one who is essentially an industrialist, it is of the greatest interest that he pleaded for the encouragement "of those who are engaged on investigations which may at present be of little or no commercial value, but which are calculated to establish the underlying general principles of the science of metallurgy". As an instance of what can be done in this direction, the aluminium light-alloy industry was quoted as a practical example.

The Royal Air Force School of Education

A NEW Royal Air Force School of Education has been opened at Wellesbourne Mountford, near Leamington Spa, and one of its main purposes is to prepare newly appointed education officers for their professional duties in the R.A.F. The School is housed for the present in temporary accommodation because in view of the nature and the importance of the work a start could not be delayed. It is intended, however, to move the School to a more permanent location when this is feasible. Education in the R.A.F. differs little in its background from education in the civilian world. Its immediate purpose is to develop those qualities of mind and character which, while adapting the officer, the airman or the boy apprentice to the exercise of particular duties, yet helps him to achieve a worthwhile personal and social life and to appreciate the duties and privileges of citizenship. On the technical side, too, it is the task of the Education Branch to contribute a theoretical content towards technical and air-crew training of R.A.F. personnel for their day-to-day duties. Naturally the means and conditions through which these tasks are performed in the Service so far differ from those outside as to involve the young education officer in a period of some difficulty until he finds his feet. It is a function of this new school of education to minimize this period, and to orientate the professional qualifications and experience of the newly appointed officer (normally a university graduate and a trained teacher, and preferably with some initial teaching experience) towards his new duties. To this end he is given instruction over a period of four weeks in the organisation and administration of R.A.F. education, in certain aspects of the theory and practice of Service teaching, in the part played by education in maintaining high standards of training and of morale, and in the methods to be employed for education in citizenship and current affairs. In addition to the lectures given by the permanent staff provision is made in the School programme for visiting lecturers of eminence in the civilian world.

It will be noted that the School lays emphasis on the scheme for the education of Service personnel in citizenship and current affairs. Indeed the School will play a part of growing significance in the further development of this scheme, and in the near future a series of courses will begin at Wellesbourne Mountford which are designed for the benefit of officers of branches other than education who may volunteer to assist in the running of discussion groups on their stations. These courses will train the officers in the technique of discussion-group leadership, and will include a factual background in citizenship and current affairs. Until the machinery of recruitment gets into its full stride, there will for some little time ahead be an acute shortage of education officers in the R.A.F. As a temporary expedient, suitable officers and others of the Service who have lesser qualifications but a liking for the work, and who volunteer for temporary duty in the Education Branch, will be accepted for duty as educational assistants—and to prepare them for this work special short courses are to be arranged for them at Wellesbourne Mountford almost immediately. They will follow the lines of the main course as for education officers, but on a somewhat lower plane. In the case of airmen volunteers, since they will be given acting non-commissioned officer rank on the successful completion of the course, training will also be given in disciplinary and other duties appropriate to the rank. Finally, it is intended that the School will, from time to time, provide specialized courses of a refresher nature to keep education officers up to date in the development of new educational techniques and of educational research.

Conference on Scientific Information Services

THE Royal Society is arranging a Conference on Scientific Information Services to be held in London during June 21–July 2. The Conference, which will consider information services from the point of view of the scientific user, in accordance with the recommendation made in 1946 by the Royal Society Empire Scientific Conference and the British Commonwealth Scientific Official Conference, will be attended by representatives of countries providing information services in English. Editors-in-chief, who will prepare memoranda as bases of discussion, have been appointed as follow for the four sections into which the Conference will be divided: Section 1, publication and distribution of papers reporting original work (Prof. J. D. Bernal); Section 2, abstracting services (Sir David Chadwick); Section 3, indexing and other library services (Dr. J. E. Holmstrom); Section 4, reviews, annual reports, etc. (Prof. H. Munro Fox). It is hoped to cover all scientific subjects, including agricultural, medical and engineering sciences. Material suggested for discussion should be submitted as soon as possible to the appropriate editor-in-chief c/o Assistant Secretary, Royal Society, Burlington House, London, W.1. Contributors are asked to emphasize the practical steps that should be taken to implement their suggestions, including the provision of finance and the requisite personnel. Admission to the Conference will be by ticket only; applications should reach the Assistant Secretary of the Royal Society before June 1.

Institution of Mechanical Engineers: Clayton Awards

THE Institution of Mechanical Engineers has divided the Clayton Prize for 1947 in equal moieties. One half, valued at £650, has been awarded to Mr. J. E. Sears, formerly superintendent of the Metrology Department of the National Physical Laboratory, for his services to engineering science and manufacture by researches and development in metrology and gauging; the other half, to the value of £650, to Mr. T. E. Beacham, consulting engineer, for his contribution to the development of the variable-pitch propeller and high-speed hydraulic pumps and other hydraulic devices by way of research, invention and design.

A number of Clayton Fellowships are to be awarded during 1948; funds for this purpose have been derived from money bequeathed to the Institution by Mr. James Clayton, who died in 1944. Mr. Clayton was chief engineer of Messrs. Courtaulds and was closely associated with the development of equipment for the rayon industry. The Clayton Fellowships will in general be awarded for a year of postgraduate study or experience in mechanical engineering or a related science, and will be worth £250–£500. Candidates must be British-born subjects not less than twenty-three years old, and must possess an approved engineering degree or similar status.

Marketing Agricultural Produce

THE written evidence submitted to the Lucas Committee on the Marketing of Agricultural Produce by Mr. Thomas Shaw, on which that Committee largely based its recommendations for setting up a system of marketing for meat when the present rationing scheme and control by the Ministry of Food ends, has now been published, together with a foreword by Dr. John Hammond (from the author, Brettenham House, Lancaster Place, London, W.C.2). Insufficient attention has yet been given to the recommendation that producer marketing boards should continue to function only up to the point of procurement where the guaranteed price under the Agriculture Act applies, and that any participation in the functions of processing and marketing beyond that stage should fall within the ambit of a national slaughterhouse board or commission. Mr. Shaw's evidence details clearly the measures which the livestock industry most needs for efficiency, including complete reorganisation of the existing slaughterhouse set-up; utilization of all by-products and elimination of unnecessary profit margins, grading, division of poorer quality meats from the fresh, the manufacturing market and measures to mitigate seasonal variations in supplies. The proposed public corporation would be given powers to approve central factory abattoir schemes; to determine the terms and conditions under which such schemes should operate; to operate grading services at the abattoir and a price-governing formula; to authorize public funds required to implement the Government guarantee of prices, and linking that guarantee with qualities of the product; to make levies covering the cost of administration and the finance of industrial research in connexion with the abattoir; and to make loans to central factory abattoir schemes. The scheme, which is intended to lead to the effective closing of the wide gap between producer and consumer prices, to relieve the State in increasing measure of its financial liability under the terms of its guarantee and lay the foundations for an efficiently operating home meat industry, has thus features in common with the development councils to be established under the Industrial Organisation and Development Act, 1947, as the functions listed for the New Cotton Board, the first of such councils to be established, clearly shows.

Royal Scottish Museum, Edinburgh

A NOTABLE feature of the activities of the Royal Scottish Museum during 1946 (Ann. Rep. 1946) was the record number of temporary exhibitions that were organised. These, all of topical interest and of strong public appeal, included the "Meet Scotland" Exhibition (which ran from August 1945 until March 1946), organised by the Museum itself; "Other Peoples Jobs", organised by the Ministry of Fuel and Power, and a special health exhibition in connexion with the City of Edinburgh's Health Week. This was divided into sections dealing with maternity and child welfare, tuberculosis, school medical services, water supply, etc. A unique aspect of this particular exhibition, and one which must certainly be unique in the history of the Museum, was the presence of nursery school infants, "who," in the words of the report, "performed their exercises and ablutions, played their games and demolished their meals, completely unaffected by the mass of admiring onlookers". In reference to these and the several other special exhibitions which were provided for by various outside organisations, Dr. D. A. Allan, director of the Museum, writes: "The scope and variety of the Museum's offerings are largely determined by the possibilities of outside assistance, and the record for 1946 provides food for thought regarding museum developments in the years ahead". The attendance figures for the various exhibitions shown on p. 3 of the report certainly justify this observation. Important donations to the Museum during the year included the Fyfe collection of Japanese *netsuké* (presented by Mrs. E. J. Fyfe). A full list of acquisitions appears at the end of the report.

British Bee Plants

MANY people are interested in learning the sources of the pollen and nectar collected by bees; others are more concerned with the pollination of flowers; while the bee-keeper often wants to know the most suitable plants for extending pastorage for his stocks. To all of these, to botanists and to other readers we can commend the booklet "British Bee Plants" as a storehouse of useful information. All the best bee-plants are dealt with, whether they are in the flower or vegetable garden, orchard, farm or countryside. Often useful hints are given regarding cultivation of particular plants, their uses and other details. Edited by A. F. Harwood, it is issued by the Apis Club, The Ways End, Foxton, Royston, at 3*s*.

British Social Hygiene Council: Summer School

"THE SCHOOLS AND THE LAND" is to be the theme of a summer school that the British Social Hygiene Council is organising at the Seale-Hayne Agricultural College, Newton Abbot, Devon, during July 30–August 13. The school will be concerned with the place of agriculture in the life of the nation, with special reference to the soil, its cultivation and improvement, grassland and arable crops, livestock husbandry, the processing and distribution of farm products, and the social and economic conditions of rural life. The school should appeal particularly to all teachers of biology, and social workers and others will be able to extend their knowledge of and sympathy with the work, outlook and social conditions of the rural community.

At the evening sessions, lectures will be given by visiting speakers, each expert in his special field. Among those who have already accepted invitations to speak are the Rt. Hon. R. K. Law, Prof. A. W. Ling, Prof. T. Wallace, Prof. D. B. Johnstone-Wallace, Mr. L. J. F. Brimble, Mr. J. H. Anderson, Mr. E. Ford, Mr. G. F. Kingston, Mr. K. C. Vear and Dr. D. A. MacPherson. The resident staff will consist of Mr. A. Roebuck, Miss H. R. Chapman, Mr. W. L. Sumner, Mr. E. Lucas, Mr. L. E. Morris, Mr. R. Weatherall and Dr. M. B. Gibbons. The fee for the School is £14 14*s*. (including £1 1*s*. enrolment fee—not returnable). This covers board and tuition. Further information can be obtained from the Secretary, British Social Hygiene Council, Dept. S.J.1, Tavistock House North, Tavistock Square, London, W.C.1.

University of Leeds: Appointments

THE following appointments in the University of Leeds have been announced: Dr. J. W. Baker, formerly senior lecturer and honorary reader in organic chemistry, to the newly established readership in the mechanism of organic reactions; Dr. C. S. Whewell, lecturer in textile chemistry, to be honorary reader in textile finishing and lecturer in textile chemistry.

University of Sheffield

THE following appointments in the University of Sheffield have been announced: O. I. Butler, senior lecturer in charge of the Department of Electrical Engineering; H. J. Cowan, lecturer in civil engineering; G. Wiseman, assistant lecturer in physiology; A. G. Macgregor, research assistant in the Department of Pharmacology and Therapeutics.

Prof. Douglas Knoop, who is retiring from the chair of economics at the end of the present session, has made a gift of money to the University to endow an economics prize, to be associated with his name, to be awarded to the student whose work in economics in the final examination for the Special Degree of B.A. has shown most distinction and promise.

Colonial Service: Appointments

THE following appointments in the Colonial Service have been announced: D. D. Campbell, agricultural officer, Uganda; H. Irving, agricultural chemist, Nigeria; D. C. Todd, agricultural officer, Uganda; G. H. Pinfield, inspector of mines, Tanganyika; L. F. Edgerley, assistant conservator of forests, Mauritius; B. R. Fuller, assistant conservator of forests, Nyasaland; S. T. Hoyle, senior agricultural officer, Lilongwe Experimental Station, Nyasaland; J. Sinclair, curator of the Herbarium, Singapore; S. Gillet (senior coffee officer, Kenya), director of agriculture, Kenya; J. T. Moon (agricultural officer, Kenya), senior agricultural officer, Kenya; C. C. Parisionos (agricultural officer, Northern Rhodesia), agricultural officer, Cyprus; A. Pickles (entomologist, Trinidad), entomologist, Nigeria; F. W. Thomas (agricultural officer, Tanganyika), senior agricultural officer, Tanganyika; J. P. Edwards (conservator of forests, Malaya), deputy director of forestry, Malaya; R. O. Roberts (chemist and petrologist, Uganda), mineralogist, Nigeria; D. F. Macpherson (senior veterinary officer, Kenya), chief veterinary officer, Nyasaland; F. L. Vanderplank (research officer, Tanganyika), entomologist, West African Institute for Trypanosomiasis.

The Night Sky in April

NEW moon occurs on April 9d. 13h. 16m., U.T., and full moon on April 23d. 13h. 28m. The following conjunctions with the moon take place: April 7d. 18h., Mercury 2° N.; April 13d. 08h., Venus 1° N.; April 18d. 02h., Saturn 4° S.; April 18d. 10h., Mars 3° S.; April 27d. 18h., Jupiter 4° N.; Mercury, in superior conjunction with the sun on April 29, is too close to the sun during the month for favourable observation. Venus is an evening star, setting at 22h. 56m. and 23h. 45m. on April 1 and 30 respectively, and shines with stellar magnitude −4 approximately during the month, about one half of the illuminated portion of the disk being visible. The planet attains its greatest easterly elongation on April 15. Mars, in the constellation of Leo, can be seen throughout the greater portion of the night, setting at 4h. 25m., 3h. 23m., and 2h. 41m., at the beginning, middle and end of the month, respectively. Jupiter, in the constellation of Sagittarius, is not visible until the early morning hours, the times of rising being 1h. 25m. on April 1 and 23h. 30m. on April 30. The planet is stationary on April 15. Saturn, in the constellation of Cancer, is visible during most of the night, setting a little before Mars, and is stationary on April 17. Occultations of stars brighter than magnitude 6 are as follows: April 13d. 20h. 31m., *k* Taur. (*D*); April 26d. 00h. 16m., 19 Scor. (*R*); *D* and *R* refer to disappearance and reappearance, respectively, and the latitude of Greenwich is assumed. There will be a partial eclipse of the moon on April 23, invisible at Greenwich, but visible over a large portion of the southern hemisphere and also over the extreme western and north-western portion of North America. The Lyrid meteors can be seen during April 18–24, but moonlight will partly interfere with the observations of this shower.

Announcements

THE governing body of the Imperial College of Science and Technology has appointed Air Chief Marshal Sir Roderic Hill to be rector of the College as from October 1, in succession to Sir Richard Southwell, who has held that office since 1942.

DR. J. CYMERMAN, lecturer in organic chemistry in Charing Cross Hospital Medical School (University of London), has been appointed lecturer in organic chemistry in the University of Sydney.

THE following have been elected officers of the Royal Photographic Society: *President*, Percy W. Harris; *Vice-Presidents*, L. V. Chilton, I. D. Wratten; *Treasurer*, H. Abbott; *Ordinary Members of Council*, Gilbert Adams, J. Allan Cash, K. H. Gaseltine, R. N. Haile, Dr. P. Hansell, T. Midgley Illingworth, Dr. S. D. Jouhar, Mrs. Rosalind Maingot, R. H. Mason, H. S. Newcombe, Alec Pearlman, Anthony Peacock, Oliver G. Pike, B. Sinkinson, A. L. M. Sowerby.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications

A 16-MeV. Betatron

DURING the past few weeks, a betatron which has been under construction by the British Thomson-Houston Co., Ltd., has come into operation, and we give some preliminary account of its properties. The magnet and coil arrangement is shown in Fig. 1. The main features of the machine are:

Maximum orbit radius	20·75 cm.
Orbit space section (where $0 < n < 1$), radial	2 ,,
axial	3 ,,
Average value of the index n	0·5
Total weight	0·85 tons
Operating frequency	50 c.p.s.
Excitation	400 volts r.m.s. 200 amp. r.m.s.
Input power	4 kW.
Peak volts per revolution at the orbit	22
Peak flux density at the orbit	2750 gauss
Electron energy at peak flux density	16·3 MeV.

The weight and kVA. are low for a betatron of this energy. This results from having a narrow orbit space and a closed central leg which leaves the annular guide-field as the only major flux in air. The accelerating and the guide fluxes are produced by two coaxial windings which lie radially on either side of the orbit. These are excited in parallel, their turns being chosen so that the accelerating flux, most of which is in the closed central leg, bears the necessary betatron relation to the guide flux. Thus the betatron is like a transformer with a loaded inner secondary winding, the core flux of which corresponds to accelerating flux, and the leakage flux of which provides the guide field. Analogous arrangements have been proposed by Kerst[1] (flux forcing) and Wideröe[2], while the General Electric Company of America has reported[3] the successful operation of such a machine. All core components are kept in contact under pressure, and we believe that this is responsible for the quietness of the machine in operation. At 400 V. excitation, the noise level is 75 phon.

Fig. 2 shows in radial section the disposition of the guide-field pole-pieces, the vacuum chamber, and, as dotted lines, the boundaries of the region of stability. The pole-pieces were designed by an electrolytic tank method which takes into account the proximity of current-carrying conductors[4]. The field fall-off exponent n in $B_r = B_0\ (r_0/r)^n$ was chosen to be $\frac{1}{2}$, making the radial and vertical oscillations of the same frequency and favouring an orbit space of circular cross-section. The space available for acceleration is partly blocked at one point by the gun, which at present reduces the radial width to 1·6 cm. A high degree of uniformity in the field around the orbit is called for in this machine on account of the limited orbit space, and so the pole-pieces are divided into quadrants, each capable of separate movement. By adjustment of the quadrants, variations in field around the orbit were reduced until their resultant was equivalent to an error of less than 0·3 per cent over one radian of circumference.

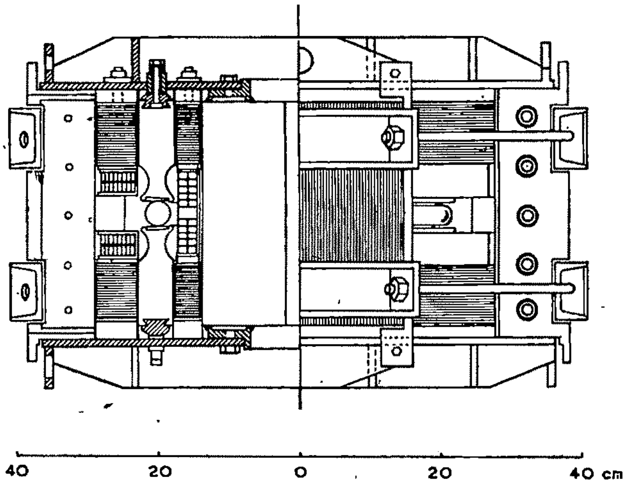

Fig. 1. GENERAL ARRANGEMENT OF A 16 MEV. BETATRON

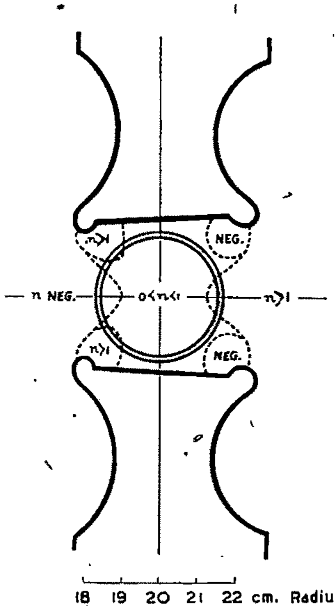

Fig. 2. GUIDE FIELD POLES, SHOWING REGIONS OF ORBIT STABILITY ($0 < n < 1$)

At the time of injection, circumferential variations in the quadrature components of the guide field are important, and, to compensate for these, coils were attached to the pole faces and fed with appropriately phased A.C. By this means the field variations at injection were reduced to the equivalent of 1 per cent (0·27 gauss) acting over one radian. Such a disturbance is estimated to produce a maximum radial oscillation amplitude of 1 cm.

Auxiliary transformers in series with one of the betatron windings supply small orbit-control voltages. An in-phase voltage controls the equilibrium orbit radius by changing the ratio between the accelerating flux and the guide flux, and a quadrature voltage serves to vary this radius during the acceleration. Due to winding resistances, there is a phase difference between the two fluxes of 0·04 radian acting in such a sense that the orbit tends to expand. This phase difference can be reduced by adjustment of the quadrature voltage; or, alternatively, the orbit radius can be allowed to drift into the target at any stage of the acceleration without using the orbit expansion pulse.

In the preliminary tests, 5 microsec. pulses were injected at 25 kV. in the orbit plane; and an output of about 0·1 r./hr. was measured at 1 metre, using an ionization chamber screened with 3 mm. of lead. Adjustments of injection voltage and timing, of orbit position, and the phase control of orbit position, were found to have the effects generally expected.

On the other hand, the gun filament current showed distinct optimum settings, above which the output decreased rapidly, suggesting that space charge may play some part in the acceptance process. The appearance at times of two stationary Geiger kicks among the random ones observed during the acceleration suggests that the orbits have a complex structure as reported for the synchrotron[5], or that some electrons, drifting to the wall, can survive and continue to be accelerated.

This acceptance and acceleration of electrons in so limited an orbit space may encourage designers to consider narrower guide-fields, more especially in very large machines.

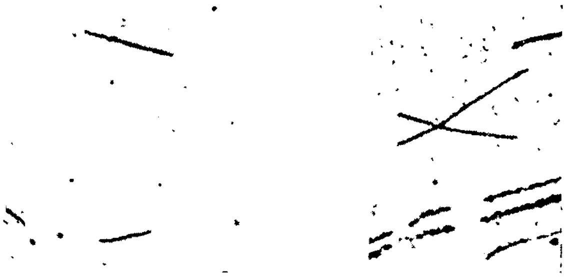
Applications of the Reflecting Microscope to the Nuclear Plates Technique

WE have found it instructive to reverse the normal microscope procedure in the examination of nuclear emulsions ; invert the plate, feed light in through the cover slip, and observe through the backing plate. With high magnification, normal objectives and ordinary glass-backed gelatine, this is not possible; but it may be done by using a reflecting microscope[1]. In this way, with oil immersion, we observed several multiple stars, and found heavy fragments which were not visible by the normal mode of examination because they were obscured by the central body of the star. In some doubtful cases, this mode of examination proved decisive in the interpretation of the event.

It was but a step to sandwich two plates, with immersion oil or Canada balsam between them (emulsion inwards), and verify that we could observe right through both emulsions with unimpaired image quality. A plate, soaked in thorium nitrate, was dried and placed against an uncontaminated plate for three days. After separation, the plates were processed in the normal way, realigned by an X-ray marking grid, and the sandwich reconstituted. The accompanying microphotograph shows two tracks which originate from a star in one emulsion and end in the other.



Since this experiment was performed, the examination of sandwiches exposed at the Pic du Midi has proved that with a normal microscope it is comparatively easy to follow the passage of particles from one plate to another with separate examination of the two plates, but only if the density of events is low. Although in our case the density of stars in the soaked plate was rather high, of the order of 20 per sq. mm., we have been able to identify the mother star of every alpha particle investigated in the second plate. These conditions provided such a stringent test of the applicability of the method in the photographic technique that we feel confident some applications, such as the dosage of radioactive substances, biological research with the auto-radiographic technique, and the measurement of long-range particles emitted by elements embedded in one of the two plates, are feasible.

The accompanying photograph shows that intimate contact between the plates was not obtained but that an air gap existed, mainly due to the large size of the plates used. With a known gap and known pressure of the gas, the 'magnification' of range thus obtained can be used for extending the field of application of the photographic plate. For example, the absorption of particles in the gas can be measured and the sign and mass of light charged particles determined by magnetic deflexion. Such an experiment is being carried out by Dr. C. F. Powell and Dr. S. Rosenblum (see following communication).

The long working distance of the reflecting microscope, which is proving useful in biological fields, will permit the examination in depth of emulsions so thick as to be beyond the range of ordinary objectives.

In the new nuclear plates the emulsion shrinkage on processing is of the order of 50 per cent, as compared with 15 per cent for the old half-tone plates, and the grain size is becoming smaller. Observation of such plates can be facilitated by using ultra-violet instead of visible light, a technique for which this instrument, being focally achromatic, is well suited.

We wish to express our gratitude to Dr. Burch for the use of the microscope, and to Dr. Burch and Dr. Powell for helpful discussion.

A New Method for the Determination of the Mass of Mesons

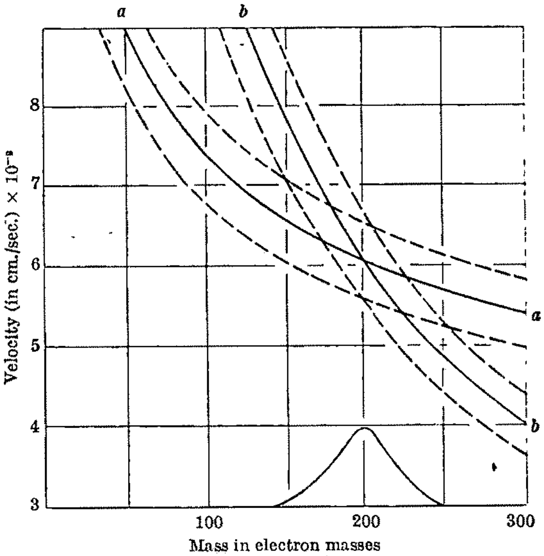
WE have recently installed at the Jungfraujoch High-Altitude Research Station an apparatus for the determination of the masses, and the signs of the electric charge, of the various types of mesons observed in photographic emulsions exposed to the cosmic radiation. In view of the importance of obtaining reliable information on this subject, and of the desirability that similar experiments should be made by other investigators, we present a brief account of the main features of the method. In doing so, we also have in mind the possibility that charged mesons may be generated artificially in the near future by means of the large synchrotrons and synchrocyclotrons now approaching completion in the United States ; and that our methods may be of use for mass determinations in this field of investigation also.

It is well known that it is not possible, at the present time, to make magnetic deflexion experiments with photographic emulsions—analogous to those which have been so successful with the Wilson expansion-chamber in experiments on cosmic radiation—by observations on the curvature, due to a magnetic field, of the trajectory of a particle in an emulsion. In examining tracks at high magnification, a measurable deflexion would correspond to such a small value of the radius of curvature that a field of the order of 10^6 gauss would be required; a field which, for work with cosmic-ray particles, it would be necessary to maintain over long periods of time. In addition, small-angle Coulomb scattering would greatly complicate the interpretation of the results. In these circumstances, we have chosen to make observations on the change in direction suffered by a particle in its passage through a gas, or a vacuum, in a magnetic field. For this purpose we have considered a number of possible geometrical dispositions of the photographic plates relative to the field; the following appears to be the most appropriate for the present experiments.

It has been observed by Bates and Occhialini that it is possible to detect and identify the tracks of single particles in two separate plates placed with their emulsions face to face[1]. A particle, moving with sufficient energy in a suitable direction, and originating in one emulsion, can leave the surface and cross the narrow air-gap to enter the second emulsion. The two component parts of the track of the same particle can be identified under the microscope. We therefore arrange two plates, in a suitable plate-holder, with their emulsions face to face, and separated by a distance of 3 mm. This assembly is placed between the pole-pieces of a permanent magnet giving a field of 8,600 gauss, so that the planes of the emulsions are normal to the magnetic field. A meson which enters the emulsion of one of the plates will, in general, have emerged from the emulsion of the other; and, in the space between the plates, it will have moved in a spiral path. If we can identify the track of the same particle in the two emulsions, then the observed change in the direction of motion in traversing the air gap, and the distance between the points of exit and entry of the particle in the emulsions, allows us to calculate $H\rho$ for the particle; the magnitude of its momentum in the plane perpendicular to the field is thus determined. Further, if the particle comes to rest in the emulsion, its observed range gives a measure of its velocity as a function of its mass. The two observations taken together define the mass of the particle.

For the successful application of this method, it is clearly necessary to define the geometrical relationship of the two plates during the exposure. For this purpose we expose the plates in their holder, before development, to a fine pencil of X-rays, and produce a succession of corresponding points, on the two plates, in the form of a geometrical grid. The relative positions and orientations of the two portions of the trajectory of a single particle, relative to the common grid, can thus be determined. The identification of the two portions of the trajectory of a particle is facilitated—and the probability of attributing two unrelated tracks to the same particle is greatly reduced—by the fact that the angles of 'dip' of the trajectory at the two surfaces must be equal; and that, for a given distance between the points of exit and entry of a single particle at the two surfaces, there is a relationship between the directions of motion at the two points. If we observe the direction of the projection of the trajectory, on a plane parallel to the surface of the emulsion, at the point of entry into one emulsion, the corresponding direction at a given point of exit in the other is determined.

In making observations, we first search one of the plates until we find the track of a meson which enters the surface; which stops in the emulsion after traversing a distance between 100 μ and 400 μ; and which has an angle of dip, β, on entering the emulsion, of less than 15°. From the observed angle of dip, we can determine the approximate position of the point of exit of the particle from the other emulsion, assuming an approximate value for its mass and that (*a*) it is positively and (*b*) negatively charged. We then search the regions of the second plate in the areas thus located, until we find a track which has the characteristics of a meson of the correct energy, and which emerges in the necessary direction.



To estimate the precision which we can expect to obtain with the method, we consider the analysis of an event in which a meson has a range of 200 μ in one emulsion; a value of $H\rho$ of 70,000 gauss-cm.; and an angle of dip of 10°. The observed range allows us to draw a curve (*a*) (see graph), showing the relation between the mass and velocity. Owing to straggling, this line must be replaced by a band, as shown. Similarly, the value of $H\rho$ defines the momentum of the particle, which allows us to construct curve (*b*). Here again, the line must be replaced by a band corresponding to an uncertainty in the determination of the change in the direction of the particle in passing between the plates, which we estimate to be ± 1°. The mass of the particle is determined within the limits corresponding to the region of overlap of the two bands, and a detailed analysis indicates that, in favourable circumstances, the 'probable error' in the determination of the mass of an individual particle will be less than 10 per cent. This result suggests that the method should be capable of a precision not inferior to that achieved in the best applications of the Wilson chamber.

It has previously been pointed out by Lattes, Occhialini and one of us that the failure to observe π-mesons, and the process of μ-decay, in an expansion chamber may be associated with the very short half-value period, τ_π, of these particles. For the successful determination of the mass of these particles by the present method, it is necessary that τ_π should exceed about 3×10^{-10} sec.

For other experiments, it is possible that a different disposition of the plates and the field would prove more suitable; but the arrangement we have employed has the advantage that the determinations of the mass do not depend critically on a knowledge of the shrinkage of the emulsion; and that, apart from losses at the edges of the plates, the track of every meson entering the surface of one emulsion must have emerged from the other.

We are greatly indebted to Prof. von Muralt, Mr. H. Widerkehr and Mr. Saige for much kindness and assistance in the establishment of the apparatus at this Station.

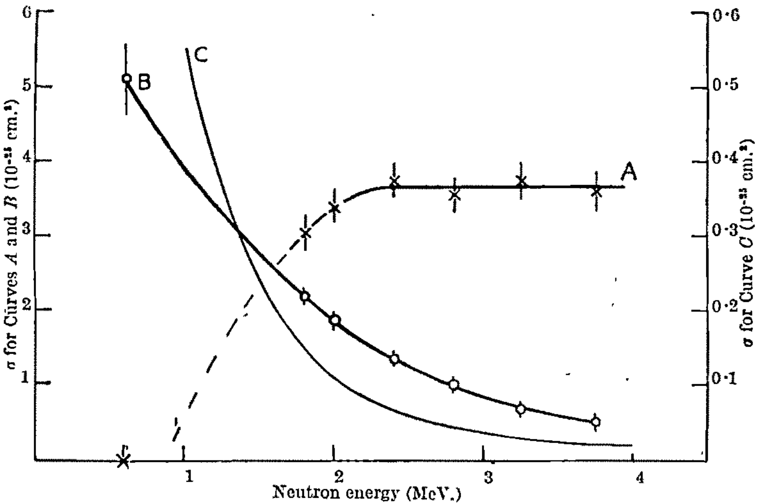
Interaction of Fast Neutrons with Indium

INDIUM has two stable isotopes, In^{115} (95·5 per cent) and In^{113} (4·5 per cent). In^{115} can be excited by an (n,n) process to a metastable-level (In^{115*}) at 340 keV. and returns to the ground-state by a strongly internally converted γ-transition with a half-life of 4½ hours[1]. Fast neutrons may also be captured in In^{115}, leading to two isomeric activities of In^{116} with periods of 54 min. and 13 sec. Both these processes may be regarded as competing in the initially highly excited compound nucleus In^{116}, and it was considered of interest to examine the absolute magnitude of the respective cross-sections as a function of neutron energy.

Indium foils were irradiated with fast neutrons from the C—D and D—D reactions produced by the Cavendish 1 MeV. high-tension set. The absolute flux of fast neutrons during irradiation was measured with a recoil ionization chamber filled with hydrogen and argon[2]. The decay of the indium after irradiation was followed with a thin-window Geiger counter, and the 4½-hr. and 54-min. activities were easily separable. During irradiation, the indium was surrounded by cadmium and boron to minimize the 54-min. activity produced by slow scattered neutrons. The remaining background activity was determined from inverse square plots. The absolute efficiencies of the β-counter for the two activities were determined by observing coincidences between the conversion electrons and the accompanying K X-rays in the 4½-hr. decay, and between the β-particles and the succeeding γ-rays in the 54-min. activity.



Curve A: Cross-section for production of In^{115*} by the (n,n) process as a function of neutron energy.
Curve B: Experimental results for the cross-section for capture in In^{115} leading to the 54-min. activity of In^{116}.
Curve C: Theoretical results of Weisskopf and Ewing for neutron capture in tin

Although there is some evidence for irregularities in the variation of inelastic scattering cross-sections with energy[3], curve A, showing the cross-section for the (n,n) process leading to In^{115*}, is smooth and flat above 2·2 MeV. The curve also indicates that a threshold for this reaction probably exists in the neighbourhood of 1 MeV. If we assume from the theory of Weisskopf and Ewing[4] that the inelastic scattering cross-section above 1 MeV. is $\sim \pi r^2$ (r is nuclear radius), that is, $\sim 2 \times 10^{-24}$ cm.^{2} for indium, then the graph shows that for primary neutrons between 2 and 4 MeV., about 20 per cent of the transitions from the excited levels in which In^{115} is left immediately after inelastic scattering lead to the metastable state. The value $\sigma = 3 \cdot 6 \times 10^{-25}$ cm.^{2} between 2 and 4 MeV. may be compared with the rough value $\sigma = 3 \times 10^{-25}$ cm.^{2} obtained by Reddeman for the excitation of the metastable-level Sr^{87*} with 2·5 MeV. neutrons[5,6]; both In^{115} and Sr^{87} have a spin 9/2 in the ground-state, and the metastable-level of Sr^{87*} is at 370 keV. above the ground-state.

Curve B shows the variation of the cross-section for the production of the 54-min. activity with neutron energy, and curve C the capture cross-sections deduced by Weisskopf and Ewing[4] for the neighbouring element tin, on the basis of the Bohr model of the compound nucleus. The general shapes of the curves between 2 and 4 MeV. are in fair agreement; but absolute values are widely divergent, by a factor of at least 20 (this is a lower limit as attention in this work was confined to the 54-min. capture activity) near 4 MeV.

In^{113} has very similar nuclear properties to In^{115}. It has a metastable state at 380 keV. with a half-life of 104 min. During this investigation, the excitation of In^{113*} by an (n,n) process has been detected by following the decay of the K X-rays accompanying conversion electrons of the isomeric transitions with a krypton-filled counter. Electrons were stopped by a layer of polythene which transmitted the X-rays, and these were distinguished from γ-rays by their strong absorption in a thin molybdenum foil; the 54-min. capture period which would conceal the 104-min. period of In^{113*} was thus eliminated. The cross-sections for the excitation of In^{113*} and In^{115*} by the (n,n) process with D—D neutrons were found to be of the same order of magnitude, just as in the case of direct excitation with X-rays[7]. The similarity in the properties of the low metastable levels of the two stable indium isotopes is analogous to the behaviour of the metastable levels[8] of the two stable odd silver isotopes $Ag^{107,109}$.

A fuller account will be published later.

I am indebted to Mr. D. West for initial discussions which led to these experiments, to Mr. K. W. Allen for his advice in the neutron flux measurements, and to Prof. M. H. L. Pryce for his comments on the results.

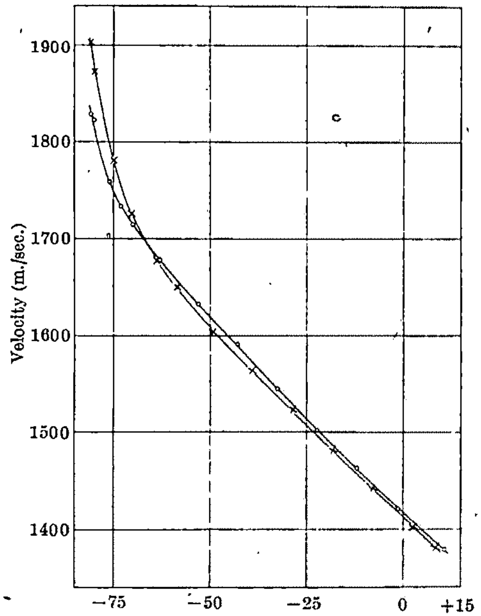
Ultrasonic Dispersion in Organic Liquids

I HAVE measured the velocity of sound, v, at frequencies between about 700 and 3,000 kc./s., and at temperatures between about + 15° and − 80° C., in the following liquids: *iso*-butyl alcohol; geraniol, $(CH_3)_2.C : CH.(CH_2)_2 . C(CH_3) : CH.CH_2OH$; di-dihydrocitronellyl ether $[(CH_3)_2 . CH . (CH_2)_3 . CH(CH_3) . (CH_2)_2]_2O$. There is evidence of negative dispersion ($\partial v/\partial f < 0$) in all three liquids, and of positive dispersion ($\partial v/\partial f > 0$) in geraniol and di-dihydrocitronellyl ether near the lower end of the temperature-range. The negative dispersion in *iso*-butyl alcohol is very small and near the limit of experimental error, but it is more pronounced in the other two liquids.



VELOCITY OF SOUND IN DI-DIHYDROCITRONELLYL ETHER AS A FUNCTION OF THE TEMPERATURE AT 689 kc./s. (○) AND AT 2102 kc./s. (×)

The accompanying graph, which refers to di-dihydrocitronellyl ether, is an example of the ultrasonic behaviour of these compounds. It will be seen that the onset of positive dispersion is marked by a more rapid increase of the velocity of sound with falling temperature than at higher temperatures.

A full account of this work will be published elsewhere.

Magnetic Susceptibility of Mica

THE magnetic susceptibilities of various natural micas have been measured by Wilson[1] and Nilakantan[2]; the latter also measuring the anisotropy. It was found that for micas which are substantially free from inclusions of magnetite, and in which the iron is therefore present in the crystal lattice, the paramagnetic susceptibility is proportional to the iron content. It was therefore surprising that Eitel and Dietzel[3] should report that synthetic mica containing only 0·05 per cent of iron is still paramagnetic, since a small cleavage flake orientated itself parallel to the magnetic field. A rough calculation shows that a mineral corresponding to their synthetic fluorphlogopite ($KMg_3AlSi_3O_{10}F_2$) should have a specific diamagnetic susceptibility of $- 0{\cdot}35 \times 10^{-6}$ C.G.S. units, and using the usual Bohr magneton value for iron of $P_B = 5$ and calculating the paramagnetic susceptibility of iron from the relation $P_B = 2{\cdot}84\sqrt{\psi T}$, where ψ is the susceptibility per gram-ion, one finds that 0·2 per cent of iron corresponds to a paramagnetic susceptibility of just $+ 0{\cdot}35 \times 10^{-6}$ C.G.S. units. A mica with a greater iron content should therefore be paramagnetic, but with less iron should be diamagnetic. Eitel and Dietzel suggested that the anomalous paramagnetism found by them was connected in some way with the highly anisotropic crystal structure of mica.

We have prepared synthetic mica[4] by the method used by Eitel and Dietzel, and a measurement of its susceptibility by the Gouy method gave a value of $1{\cdot}60 \times 10^{-6}$ C.G.S. units at a field of about 9,000 oersteds between the pole pieces for a specimen containing 0·04 per cent of iron. The paramagnetism thus appeared to be very high indeed, and would correspond to a Bohr magneton value for iron of $P_B = 25$.

Closer investigation has, however, shown that this apparent large paramagnetism is spurious, and that the observed effect is really due to the ferromagnetism of inclusions of magnetite in the synthetic mica. This conclusion is based on the following facts: (1) the susceptibility decreases with increasing field strength; (2) a large part of the iron in the synthetic mica prepared by us can be washed out by dilute sulphuric acid, although such a treatment scarcely affects a natural mica which is free from inclusions; thus confirming that magnetite inclusions are present in the mica prepared by us, and hence in that prepared by Eitel and Dietzel also. Although we have not been able to extend our measurements to sufficiently large fields, our results indicate that at very large field strengths this synthetic mica should become diamagnetic, the ferromagnetic inclusions then being saturated and the intrinsic diamagnetism of the mica causing a cleavage flake to set perpendicular to the field.

We carried out similar experiments with a sample of the synthetic fluorphlogopite prepared by Middel[5] and found that in this case magnetite inclusions were substantially absent, although the iron content was about the same (0·05 per cent), since the mineral was diamagnetic at all fields. This is no doubt due to the very much slower cooling rates used by Middel during the crystallization of the mica. (He prepared melts of up to 100 kgm., while Eitel and Dietzel and ourselves prepared melts of only about 200 gm.) The specific susceptibility of Middel's synthetic mica was measured by us, using the Rabi method. Different values for the specific susceptibility parallel to the cleavage plane were obtained for different crystals, ranging from $-0 \cdot 17 \times 10^{-6}$ to $-0 \cdot 29 \times 10^{-6}$ c.g.s. units. This variation would indicate that the small iron content is unevenly distributed throughout the mica crystal lattice.

A Large Field Compensator for Measurement of Birefringence

In the measurement of stresses in glass using polarized light, it is usual to employ some form of compensator in which the amount of birefringence varies uniformly across the field of view and passes through zero value at the centre. This gives a series of parallel fringes when viewed suitably between crossed polarizer and analyser. With white light the central fringe is black, and serves as a useful index.

In the Babinet compensator the uniform variation of birefringence is obtained by superimposing two narrow-angle quartz wedges, cut with their optic axes at right angles, with the thick edge of one adjacent to the thin end of the other. The same effect can be obtained by uniformly bending strips of a photoelastic material in a plane perpendicular to the direction from which it is to be viewed. The central black fringe corresponds to the neutral plane of the bent beam so formed, and fringes due to tension and compression are seen on either side of it. A compensator based on this principle has been described by Holmes[1] and consists of a strip of plate-glass uniformly bent in a suitable bending device, with the plane of bending parallel to the polished faces of the glass.

It has been found possible to produce the same effect by bending a strip of the resin *CR.* 39 in a similar way. The strain pattern can be 'frozen' into this material and the bending device afterwards discarded. A clamp is used which, by means of a screw, can be made to apply equal and opposite couples to the two ends of a strip of the material, so that it is bent uniformly in a plane parallel to the original faces of the sheet from which it was cut. The clamp holding the strip loosely in an unstrained condition is placed in an oven maintained at 105° C. After about ten minutes the sample is removed from the oven and the screw quickly tightened to give the desired strain pattern in the strip. After cooling to room temperature and removal from the clamp, the strip retains the strain pattern, which does not alter appreciably after the first 24 hours. Most of the unwanted end portions where the couples were applied, and where the bending is not uniform, may then be sawn off without affecting the system of parallel fringes extending over the remainder of the strip.

Strips 14 in. × 2 in. of various thicknesses have been used; but the dimensions are limited only by the sizes of clamp and oven available. With this size, parallel fringes cover an area of approximately 8 in. × 2 in., and up to three fringes on either side of the neutral fringe have been obtained in a thickness of ¼ in. A limit is set to this number by the flexural strength of the material when hot. The curvature of the strip with this amount of strain is apparent, but for most applications is not objectionable. By using a number of strips built up into a single unit the number of fringes may be increased; or alternatively the amount of curvature for the same number of fringes may be decreased.

Two strips of 'Polaroid' with their planes of polarization suitably orientated may be used as polarizer and analyser with the compensator. This combination forms a direct vision strain-viewer with a large field of view which may be used with any bright background and needs no projection system. One of the strips of 'Polaroid' may conveniently be mounted on one surface of the compensator and the other in a suitable holder, so that the whole apparatus comprises two compact units. Since no setting up is required, the compensator used in this way is useful for the rapid examination of stresses in glass both under laboratory and also under factory conditions.

The compensator described is superior to the quartz type as regards size of field, and may be of some interest for the evaluation of the degree of birefringence in problems other than the special application in this laboratory.

The work on this compensator was carried out in the Research Laboratory of Messrs. Pilkington Brothers, Ltd., who have kindly agreed to publication.

New Bands in the Schumann–Runge System of the Oxygen Molecule

Oxygen produced by heating potassium permanganate crystals was excited by a high-frequency (750–850 kc./sec.) discharge (output power less than 10 watts) and the spectra protographed both in the visible and in the ultra-violet regions by a Fuess glass prism spectrograph and a small (baby) quartz prism spectrograph respectively. A good many of the more intense bands of the Schumann – Runge system were found on both our plates. On attempting to extend the system, we discovered that a number of new bands present on our plates, but not reported by previous workers, fitted in the $(v'v'')$ scheme of this system. These new bands (ν_{vac}) along with our proposed quantum assignments are given in the accompanying table.

S.N.	ν_{vac}	Proposed (v',v'')	S.N.	ν_{vac}	Proposed (v',v'')
1	22277	(8,25)	14	28212	(7,19)
2	22616	(0,20)	15	29824	(4,16)
3	22804	(9,25)	16	30361	(1,14)
4	23208	(6,23)	17	30416	(3,15)
5	23270	(8,24)	18	31005	(2,14)
6	24120	(4,21)	19	31056	(4,15)
7	24244	(6,22)	20	31625	(1,13)
8	24285	(8,23)	21	32252	(6,15)
9	24605	(3,20)	22	32291	(2,13)
10	26452	(4,19)	23	35828	(8,13)
11	27065	(5,19)	24	36575	(7,12)
12	27368	(2,17)	25	37327	(6,11)
13	28005	(3,17)	26	40776	(5,8)

These bands are very strongly degraded to the red. The distance between the head and the origin of a band of this system is found to be less than 0·5 A. This gives to most of the bands of this system a confused line-like structure with instruments of small dispersion such as have been used in the present case. However, their existence as bands is definite on our plates.

The quantum assignment of these new bands gives vibrational differences (both in the initial and in the final states) of the expected magnitudes. It is, however, to be noted that appreciable discrepancies in the initial vibrational differences for the level (2–3) and in the final vibrational differences for the levels (12–13) and (13–14) appear on account of too low (λ) values of the bands (3,17) and (0,14) (as obtained by us in the present case).

Since the Schumann – Runge system is in general difficult to observe in emission by other methods of excitation, it appears that the high-frequency discharge is especially suited for obtaining this system in emission. Its appearance here is due to the selective excitation property of the latter.

In conclusion, it may be mentioned that Flory[1] thinks that the $^3\Sigma_v^-$ state predissociates before the bands with $v' > 2$ can be obtained in emission. But he gives no rigorous proof for such a predissociation. The existence on our plates of the new bands with $v' > 2$ (most of which have been marked on the enlargements of the spectrograms and will be published along with the details), however, is quite certain. If theoretical conclusions, based on the present accepted structure of the oxygen molecule, question the existence of these new bands of the Schumann – Runge system in emission, reconsideration is necessary of the structure of the oxygen molecule (a conclusion we have arrived at from many other points of view also).

I wish to thank Prof. R. K. Asundi, of the Benares Hindu University, under whose guidance the work has been done.

Meteor Whistles

MANY observers have reported Döppler-effect heterodynes in the background of received high-frequency broadcast signals. The accepted explanation of the whistles is that waves received after reflexion from ionized meteor trails have undergone a frequency-shift, relative to the waves received by a more direct path. Usually, the pitch of the heterodyne descends to zero. Chamanlal and Venkataraman[1] suggested, in 1941, that the descending pitch was the result of the meteor being rapidly retarded in velocity. More recently, Sir Edward Appleton and Mr. R. Naismith[2] proposed an alternative explanation of the change of pitch, which is ascribed to the reduction of the difference between the two path-lengths that occurs as the meteor, travelling tangentially to the observer, approaches the minimum distance.

The latter explanation, involving only the changes in geometry of the reflected ray, is more acceptable because it does not fail to account for the less frequent observations in which the pitch of the heterodyne first descends, passes through zero and then rises again. We have observed these 'doublet' whistles on numerous occasions, although they occur only 1 or 2 per cent as frequently as the single whistles with a falling note. We believe that the dual whistles are caused by meteors that do not approach the earth directly but pass through the atmosphere sufficiently near to earth to ionize a track and to reflect radio signals. The relative velocity of the meteor to earth may, in these cases, be sufficient for the meteor to avoid being deflected and 'captured'.

We used the word 'tadpole' to describe meteor whistles when they were first noted here some years before the War. Unfortunately, the significance of the heterodynes and their connexion with meteoric ionization was only guessed and could not be proved until after short-wave cathode-ray direction-finding apparatus became available to us in 1940, and it was possible to make simultaneous observations of radio direction and of the direction of visible meteor trails in the night sky. By this time, other observers had published conclusions similar to ours.

Since that date, we have made numerous recordings of the phenomena, and it may be of interest to note the results of our observations, as follows:

(1) At the moment when the whistle reaches zero pitch, there is a large increase in the strength of the received signal, as stated by other observers. Amplitude changes of at least 20 to 1 have been recorded here, on carrier frequencies between 15 and 22 Mc./s.

(2) Whistle durations of up to 7 sec. have been followed by 'bursts' of high-amplitude reception sometimes lasting for 10 sec. and, more rarely, for so long as 40 sec.

(3) Of the total of audible whistles, only 1 or 2 per cent have been 'doublets', as noted above. Others have all been falling in pitch.

(4) Whistles have been most commonly heard at the times of year which correspond with the arrival dates of known meteor streams. They are very seldom audible during day-time. The minimum observations occur in the period between about two hours after sunrise and two hours after sunset. Following this, they become audible in increasing numbers, with a maximum about the time of sunrise, falling off rapidly thereafter.

(5) Correlation between visible meteor trains and direction-finder bearings of falling-note radio whistles can often be obtained. We have not yet succeeded in correlating the doublet whistles in this way, perhaps because the visible meteor trails would be too near the horizon of the observer.

(6) It would appear that conditions for reflexion usually fail when the radio whistle reaches a pitch of about 2 kc./s. The whistle heterodyne seldom reaches a higher frequency than this, either when falling or rising.

(7) Amplitude 'bursts'—but without previous heterodyne whistles—have been noted on amateur radio transmissions at frequencies of 60 Mc./s. The bursts on this higher frequency appear to be of shorter duration, possibly with greater amplitude change, than those experienced in the lower frequency bands. Although difficult to record on account of the short duration, the increase in signal-level seems often to reach 35 db. (that is, 56 : 1 ratio).

Open-Hearth Furnace Models

LARGE-SCALE trials recently carried out on open-hearth furnaces[1] emphasize the need for more fundamental knowledge of the flow of fuel, air and combustion products through the furnace chamber. To obtain such information by experimental work on a production furnace presents extreme difficulties due to the high working temperature and the necessity of avoiding interference with production. The problem of flow through such complex ducts having also proved too difficult to solve mathematically, it was decided to use a model technique. Models of open-hearth furnaces with differing port designs were therefore made in 'Perspex' on a 1/24 linear scale.

Both fuel gas and air are represented in the model by water. The two flows ('air' and 'gas') to the model are separately metered and can be controlled so that the Reynolds numbers at the incoming ports are equal to the corresponding Reynolds numbers on the actual furnace. The partition of 'waste gases' between outgoing gas and air ports can be similarly controlled by adjusting valves. Flow through the model has been studied in three dimensions using a variety of methods. At present use is made of fine aluminium particles suspended in the water, and illuminated in any desired direction by means of an intense sheet of light. By suitably compounding the two-dimensional patterns thus obtained, a three-dimensional pattern of flow throughout the furnace can be built up. The patterns are recorded photographically, the light source being either (*a*) an over-run 2 kW. line filament lamp; or (*b*) a specially designed Mullard discharge tube, the duration of flash from which is adjustable.

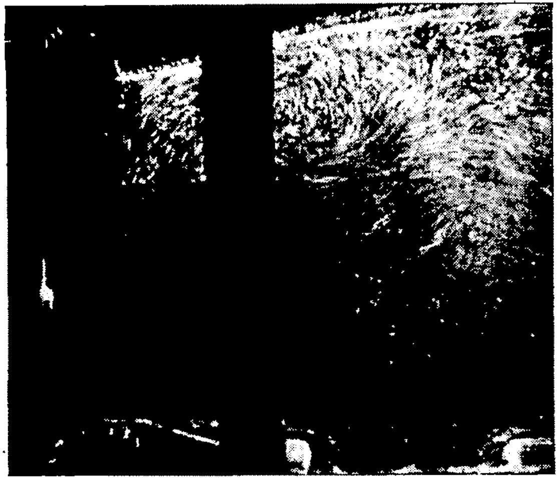

Fig. 1

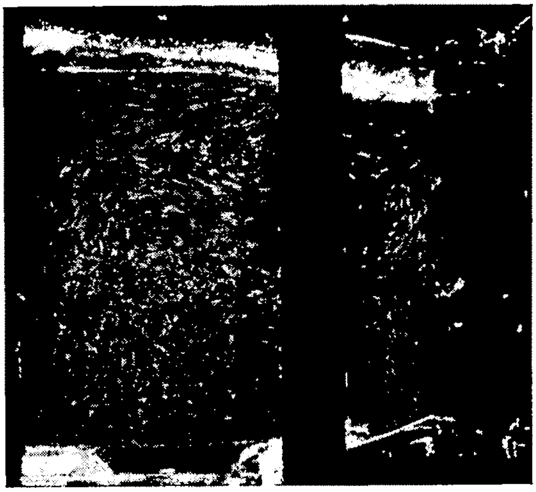

Fig. 2

The work is still at an early stage; but preliminary conclusions with a model of a Maerz open-hearth furnace show:

(1) At the incoming end of the furnace a major vortex is produced on either side of the incoming gas stream over a wide range of flow (Fig. 1). The vortices are asymmetrical and are actually three-dimensional in character.

(2) In the centre of the furnace there is a region of instability in which the particles are moving in all directions.

(3) Near the outgoing end of the furnace, the flow tends to align itself before entering the outgoing ports (Fig. 2) and is particularly rapid along the back-wall.

The general eccentricity of flow is also apparent from a study of the photographs. In particular, Fig. 1 shows that the incoming gas stream is deflected towards the furnace back-wall, although the centre-line of the gas ports is parallel to the centre-line of the furnace. This is of practical interest as it is normal for the line of the gas port on a furnace to be inclined towards the front-wall at an angle of about 3° to the centre-line, in order to counteract the tendency for the flame to be diverted towards the back-wall. The need for this correction has generally been ascribed to air inleakage through the doors, whereas it would appear to be desirable purely because of the asymmetrical furnace design.

It is of interest to note that a somewhat similar flow pattern has been found in the flame tubes of jet engines[2].

A report giving detailed results of the present work will be published elsewhere.

Effect of Ionic Charges on the Energy and Entropy of Activation of Heterolytic Reactions

A PREVIOUS investigation[1] of the influence of the carboxylate-ion substituent on the kinetics of solvolysis of organic bromides, *R*Br, showed that in the two series (*R* =)

$$\mathrm{CH_3} \qquad \mathrm{CH_2(CO_2^-)} \;\vdots\; \mathrm{CH(CO_2^-)_2} \qquad (1)$$

$$\mathrm{CH_2Me} \;\vdots\; \mathrm{CHMe(CO_2^-)} \qquad \mathrm{CMe(CO_2^-)_2} \qquad (2)$$

there is (where indicated) a change of mechanism from S_N2 to S_N1 as the CO_2^--groups accumulate. We have now investigated the kinetics of the solvolysis of the bromides of two more series (*R* =),

$$\mathrm{Me_3C} \qquad \mathrm{Me_2C(CO_2^-)} \qquad \mathrm{MeC(CO_2^-)_2} \qquad (3)$$

$$t\text{-}\mathrm{BuCH_2} \qquad t\text{-}\mathrm{BuCH(CO_2^-)} \qquad t\text{-}\mathrm{BuC(CO_2^-)_2} \qquad (4)$$

and the results permit consideration of the further series (*R* =)

$$\mathrm{HC(CO_2^-)_2} \quad \mathrm{MeC(CO_2^-)_2} \qquad t\text{-}\mathrm{BuC(CO_2^-)_2}. \qquad (5)$$

Throughout series (3), (4) and (5), mechanism S_N1 prevails; and the main interest of the new results relates to the effect of the carboxylate-ion substituent on the unimolecular rate-constants k_1, and on their parameters *E* and *B* in the Arrhenius equation $k_1 = B \exp - E/RT$. The measured reaction is in all cases the heterolysis (ionization) of the CBr-bond. The data are in the accompanying table.

RATE CONSTANTS AND ARRHENIUS PARAMETERS FOR THE UNIMOLECULAR SOLVOLYSIS OF BROMIDES

Series	Solvent	*R* in *R*Br.	k_1 (25°) (sec.$^{-1}$)	*E* (kcal.)	*B* (sec.$^{-1}$)
3	"60%" EtOH—H$_2$O	[2]$\mathrm{Me_3C}$	$3{\cdot}8\times10^{-3}$	21·7	$3{\cdot}4\times10^{13}$
		$\mathrm{Me_2C(CO_2^-)}$	$5{\cdot}6\times10^{-5}$	27·8	$1{\cdot}6\times10^{16}$
		$\mathrm{MeC(CO_2^-)_2}$	$1{\cdot}6\times10^{-5}$	28·0	$6{\cdot}5\times10^{15}$

3	H$_2$O	[1]$\mathrm{HC(CO_2^-)_2}$	$3{\cdot}4\times10^{-8}$	32·5	$2{\cdot}5\times10^{16}$
		[1]$\mathrm{MeC(CO_2^-)_2}$	$8{\cdot}7\times10^{-6}$	30·3	$1{\cdot}6\times10^{17}$
		t-$\mathrm{BuC(CO_2^-)_2}$	$7{\cdot}3\times10^{-5}$	28·8	$9{\cdot}7\times10^{15}$

We shall require one further set of figures, namely, the following approximate values for a secondary alkyl bromide: k_1 (25°) = 10^{-7} sec.$^{-1}$, $E = 26$ kcal., $B = 10^{12}$ sec.$^{-1}$; they are deduced by interpolation, since no direct determination is yet available[4], though consistent figures for the secondary chloride, *t*-BuCHMeCl, have recently been obtained by Mr. R. J. L. Martin. The following statements can be made: (i) A replacement of H by Alk at the seat of substitution of an alkyl bromide increases k_1 by a factor of approximately 10^4; and a second such substitution repeats the effect. (ii) These effects on rate are mainly (that is, to the extent of about three-quarters of the logarithmic change) due to changes in *E*, each replacement of H by Alk decreasing *E* by about 4 kcal. (iii) The replacement of H by CO_2^- increases k_1 by factors of order approximately 10^3, and therefore the replacement of Alk by CO_2^- reduces k_1 by small factors of average order approximately 10^1. (iv) This small effect on rate, when it arises from a *first* replacement of Alk by CO_2^-, results from the near-cancellation of two large effects; for the replacement increases *E* by 6–8 kcal., and also increases *B* by factors 10^3–10^5. (v) The similarly small effect on rate, arising from a *second* replacement of Alk by CO_2^-, results from small effects on *E* and on *B*.

The groups Alk and CO_2^- both repel electrons. The effects (i, ii) due to Alk have previously been interpreted as being mainly of internal polar origin[4]. Quite similar effects should also originate in the group CO_2^-. However, the important qualitative difference between Alk and CO_2^- is the ionic charge on the latter; and we may now consider briefly how this might produce the special effects (iii, iv, v) which arise when we replace one group by the other.

Such effects are considered to be due to solvation. The principal differences of solvation energy should arise in the initial states of these halide ionizations, because in the initial states such charges as are present are relatively localized, whereas in the transition states the charges are distributed, with partial neutralization of any pre-existing charges. Thus the increase of 6–8 kcal. in *E*, which we observe on introducing a first CO_2^--group in place of the comparably electron-repelling group Alk, is attributable essentially to an additional solvation energy in the initial state, which is only partly compensated in the transition state.

The corresponding increase in *B* by factors 10^3–10^5 is similarly ascribed to pre-fixation of the solvent. Relatively to co-ordinate axes imbedded in a reactant molecule, certain solvent molecules must be restricted by an ionic charge in the initial state to positions which are geometrically close to those which solvating solvent molecules will be required to occupy in the transition state; and thus their displacement from one set of positions to the other will be accompanied by a smaller entropy decrease than would have been involved in the absence of the initial charge.

The large increase in *E* is not repeated on the introduction of a second CO_2^--group, because only one such group can be involved with the forming carbonium ion in the transition state, and hence the second will produce closely compensating amounts of extra solvation energy in the initial and transition states. Again, the large effect on *B* will not be repeated, because, while one CO_2^--group will guide the solvent molecules as described, the other will solvate so similarly in the initial and transition states that it can contribute little to the entropy difference.

The rates of reactions in solution are often considered on the basis that certain frequency factors (of the order of a vibration frequency for unimolecular reactions, and of a collision number for bimolecular reactions) are 'normal', so that it is chiefly the departures from such values which merit discussion. The theories which proceed on these lines, having been evolved by extension from studies of gaseous reactions, do not sufficiently make solvation a prime consideration in the determination of 'normality'. Our point of view is that solvation energy and entropy are the most characteristic determinants of reactions in solution, and that for this class of reactions no norm exists which does not take primary account of solvation. Further illustration and discussion will be offered in papers being submitted to the Chemical Society.

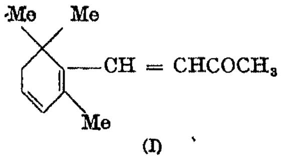
Synthesis of Dehydro-β-Ionone

The elegant brominating reagent, N-bromosuccinimide, has been employed by Karrer[1] to prepare *bis*dehydrolycopene from the acyclic carotenoid, lycopene. It has now been shown that the cyclic compound β-ionone reacts in a facile manner with this reagent, giving a bromo-derivative which on dehydrobromination with diethylaniline yields dehydro-β-ionone (I), b.p. 75° at 1 mm. mercury pressure, n_D^{22} 1·5497. The absorption spectrum exhibited maxima at 2210 A. and 3380 A. ($\varepsilon = 7,000$ and 9,000 respectively). The product was characterized by the formation of a semicarbazone (m.p. 144–146°) and a 2 : 4-dinitrophenylhydrazone (m.p. 150–151°).



(I)

The synthetic potentialities of dehydro-β-ionone for the preparation of dehydro-compounds of the vitamin A type are now under investigation in these laboratories. The synthesis of dehydrovitamin A_1 by the above approach would be of considerable interest, since this structure is one that has been suggested[2] as representing vitamin A_2.

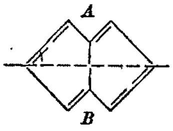
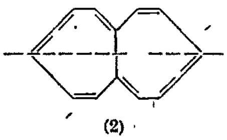
The Non-Benzenoid Aromatic Hydrocarbon Pentalene

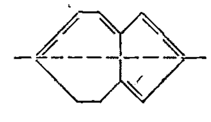
It is an interesting fact that neither pentalene (1), nor heptalene (2), nor any derivatives of them have been definitely reported as being synthesized[1] or found to occur naturally. Azulene (3) is, on the other hand, a substance which can be made by the established procedures of organic chemistry and it is known in Nature.



(1)

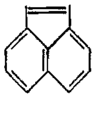


(2)



(3)

When a study is made of these molecules by the valence-bond method first developed by Hückel[2], pentalene and heptalene prove to be different in one respect from azulene, and from other common hydrocarbons: the wave functions describing the most stable state of their π-electrons are antisymmetrical with respect to the axis indicated in the diagrams. In contrast, the π-electron wave functions of azulene, of all hydrocarbons built up from six-membered rings and of other common hydrocarbons, have the full molecular symmetry in their ground-states. An example of a possible exception to this statement is provided by acenaphthylene, which is being investigated. It is not obvious, however, whether this difference between the known hydrocarbons and the unknown pentalene and heptalene is connected with the difficulty of obtaining these latter structures.



In an earlier paper, Coulson and Rushbrooke[3] have examined these molecules by the molecular orbital approximation. In that method, all molecules with an even number of π-electrons are described as having symmetrical ground-states, so that the distinction of symmetry does not emerge. Coulson and Rushbrooke did, however, find that the molecular orbital method encounters a difficulty in dealing with these molecules, but the same difficulty arises with the known molecule azulene as with the other two.

Details of energies, bond orders, etc., are being reported elsewhere, especially for pentalene. According to the calculations, this molecule should possess considerable resonance stabilization (*c.* 40 kcal.), and it has been confirmed in the calculations that the triplet state lies above the lowest singlet, so that the unsymmetric state discussed above is, in fact, the lowest of all the states. A calculation of bond orders by the method of Penney[4] gives the unusual result that the central bond (*A*—*B* in formula 1) has a small negative bond order, expressing the fact that the π-electrons exert a considerable repulsion across that bond; the large resonance energy, however, confirms that the overall effect of π-electron interaction, when all the resonance possibilities are considered, is strongly stabilizing.

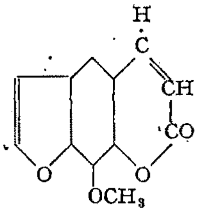
Xanthotoxin from the Fruits of *Ammi majus* L.

Fahmy and Abushady[1] have isolated from the fruits of *Ammi majus* L. a crystalline product to which they gave the name 'ammoidin'. We wish to express our gratitude to them for supplying us with this material and for allowing us to determine its constitution. We have found that the substance does not contain active hydrogen or an acetyl group[2], but it contains one methoxyl grouping. Analysis of ammoidin gave the formula $C_{12}H_8O_4$, and after degradation we found that it possesses the constitution:



This constitution is identical with that of xanthotoxin, which had been isolated by Thoms from the fruits of *Fagara xanthoxyloides*[3] and from the berries of *Luvanga scandens* by Bose and Mookerjee[4], and which had been synthesized by Späth and Pailer[5]. We have found that ammoidin possesses the same properties as those described for xanthotoxin; for example, the product, m.p. 233°, was obtained from ammoidin under the same conditions which were followed for the preparation of nitroxanthotoxin[3]. The identity of ammoidin and xanthotoxin was finally proved by the mixed melting point (no depression) with an authentic sample of xanthotoxin; this was kindly done for us by Prof. Ebert of the University of Vienna.

Pharmacological aspect. The powdered fruits of *Ammi majus* are taken by mouth by the public in Egypt to cure leukoderma; the patient exposes the leukodermic patches repeatedly to the sun for half an hour after administration of the crude drug.

Xanthotoxin (ammoidin) has been given internally to leukodermic patients or applied as a paint over the leukodermic patches, resulting in the same curative effect as shown by the crude drug but without the toxic effects of the latter[6].

Note added in proof. Fahmy and Abushady have isolated a second crystalline substance which we have shown to be imperatorin[7].

Active Penetration of Fat into Adipose Tissue

WHEN adipose tissue of the rat, depleted of part of its fat by prolonged hunger, is incubated with blood or serum of the same rat, a decrease in the fat content of the medium can be demonstrated. Killing the tissue by heating to 80° C. abolishes this effect. The addition to the medium of sodium fluoride ($M/20$ or $M/40$), or of sodium cyanide ($M/500$) also completely inhibits the disappearance of fatty acids. Sodium azide ($M/1,000$) had no inhibiting effect. The most marked decrease in the fat content of the medium was obtained with adipose tissue and blood of rats starved to 25 per cent loss of weight. With fat-laden adipose tissue of normal rats the effect was negligible or absent. No decrease in the fat content of the blood was found when the incubation was carried out at room temperature. The accompanying table summarizes these results.

No. of expts.	Tissue	Medium	Average decrease in fat content of medium
17	Depleted groin fat	Blood of same rat	40±2·6 per cent
5	,, heated to 80° C.	,, ,, ,,	0
6	Fat-laden groin fat	,, ,, ,,	10±8 ,, ,,
4	Depleted groin fat	,, with $M/20$ NaF	0
4	,, ,, ,,	,, with $M/40$ NaF	5 ,, ,,
5	,, ,, ,,	Serum, with $M/500$ NaCN	0
3	,, ,, ,,	Blood, with $M/1,000$ NaN_3	34 ,, ,,
3	,, ,, ,,	Blood, at room temperature	0

100 mgm. of groin fat are cut with scissors to a fine brei and incubated with 1 ml. of blood or serum, in air, at 38° C. The fatty acid content is estimated in 0·1 ml. of the medium after half an hour (initial value) and after 3½ hours of incubation, according to the method of Marenzi and Cardini[1].

The quantity of fatty acids disappearing from the blood, by incubation with depleted adipose tissue for 3 hours, is between 1 and 2 mgm. The oxidation of fat by the tissue accounts for only 0·025 mgm. (calculated from the value of 0·18 mm.[3] oxygen consumed per mgm. fat-depleted adipose tissue per hour). The main quantity of the disappearing fat must thus have been taken up by the tissue without any profound change.

The results of these experiments show that the penetration of fat into adipose tissue is an active process, depending on the physiological activity of the tissue.

The physiological and pathological conditions influencing this penetration are under investigation.

Peripheral Action of Botulinum Toxin

AN investigation has been made of the pharmacological properties of *Cl. botulinum* (type *A*) toxin. Rabbits injected intravenously with the toxin developed severe œdema with focal hæmorrhages in the lungs. These lung lesions were also found when 'local' botulism was produced in a number of tissues, but with larger doses of toxin. It was therefore possible to achieve a local concentration of toxin sufficiently high to paralyse certain nerve-endings without killing the animals prematurely by the injury to the lungs.

Intra-ocular injections of the toxin produced a total paralysis of the nerves to the sphincter pupillæ, which failed to react to light or to stimulation of the oculomotor nerve. This action was analysed and was found to be due neither to any injury of the smooth muscle itself nor to a neuro-muscular block of the type produced by atropine (as suggested by Edmunds and Long[1]), since the sphincter reacted normally to acetylcholine.

The injurious effect of the toxin appears, therefore, to be on the cholinergic nerve fibres proper and is restricted to them, since stimulation of the cervical sympathetic nerve still dilates the pupil, and reflexes originating from the cornea are not abolished. This shows that the adrenergic and sensory nerve fibres concerned, although exposed to the same concentration of toxin within the eye, are not affected in the same way as are the cholinergic fibres.

In similar experiments on voluntary (extrinsic ocular) muscles paralysed with toxin, normal responses to acetylcholine were recorded. This differentiates the botulinic effect on skeletal muscle from that of curare poisoning, and again points to a lesion of the motor nerve-endings which are cholinergic.

Lastly, it has been found that despite its high molecular weight (900,000–1,130,000 [2]), this protein is able to pass out of the eye into the general circulation, which suggests that it must be capable either of inducing a change in capillary permeability to allow its passage, or that it is broken down to a smaller diffusible molecule which is still neurotoxic.

It is hoped to publish a full account of this work elsewhere, and further investigations are in progress.

Secondary Thickening in Excised Tomato Roots

White[1] has stated that secondary thickening does not occur in excised root cultures. Some of our cultures of tomato ('Best of All') which had been kept without transfer for five to six months were recently submitted to anatomical investigation, and were found to have developed a considerable amount of secondary xylem, though the occurrence of properly differentiated secondary phloem has not yet been demonstrated. The nature and extent of the secondary xylem can be illustrated by reference to two examples.

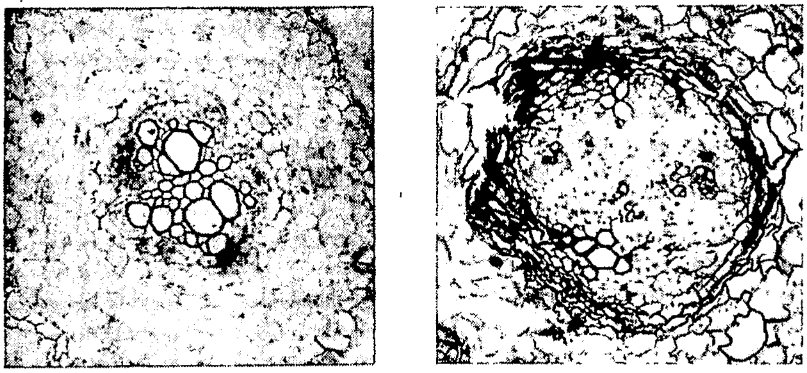

Fig. 1 Fig. 2

Transverse sections of excised tomato roots. × 120

Root culture Passage 5, No. 41, growing on White's synthetic medium, exhibited in its older parts a patchy brown discoloration accompanied by a distinct thickening. Sections of these regions contained considerable quantities of secondary xylem. Most of the sections were characterized by an almost normal distribution of secondary xylem (Fig. 1), though some showed an anomalous condition in which a ring of lignified tissue containing vessels enclosed a central mass of thin-walled cells, the whole clearly formed by the activity of a cambium-like layer.

Culture Passage 1, No. 13, growing on White's yeast medium, also yielded some sections with normally distributed secondary xylem and others showing pronounced abnormality (Fig. 2). Here, on one side of the diarch primary xylem, repeated and disorderly cell divisions have produced a mass of callus-like tissue, only a few cells of which are differentiated into xylem elements. On the other side of the primary xylem, no corresponding development has occurred.

These examples demonstrate the occurrence of secondary xylem, but also show that the cambial activity is frequently seriously disorganised and results in the production of conspicuously abnormal structures. The exact age at which secondary thickening begins and the extent to which the process is influenced by cultural conditions are now under investigation, and will form the subject of a subsequent report.

Second Occurrence and Persistence of the Amphipod *Orchestia bottæ* M. Edwards in Britain

The amphipod *Orchestia bottæ* M. Edwards was first recorded in Britain by Gordon[1], who found it on the banks of the Thames at Richmond in 1942. This species, from the Mediterranean area, appears to be spreading and invading the freshwater systems of Europe. Dr. Gordon quotes records of its being taken in France (Cambrai, Nancy), Holland (80 km. from the sea), Belgium and Germany. The object of this note is to record that in July 1946 we found it in large numbers, adult and very young, in the damp roots of grass just above the water on the right bank of the Thames at Oxford, about half-way between Folly Bridge and Iffley Bridge; this is 92 miles upstream from the first lock (Teddington). In July 1947, one of us (A. J. C.) found it again in the same spot, still quite abundant though perhaps less so than in 1946. The severity of the spring had not apparently affected it.

We are indebted to Dr. G. M. Spooner of Plymouth for identifying our specimens. Dr. Gordon, of the British Museum, who has also seen specimens, confirms that it is the same species as that found by her at Richmond in 1942.

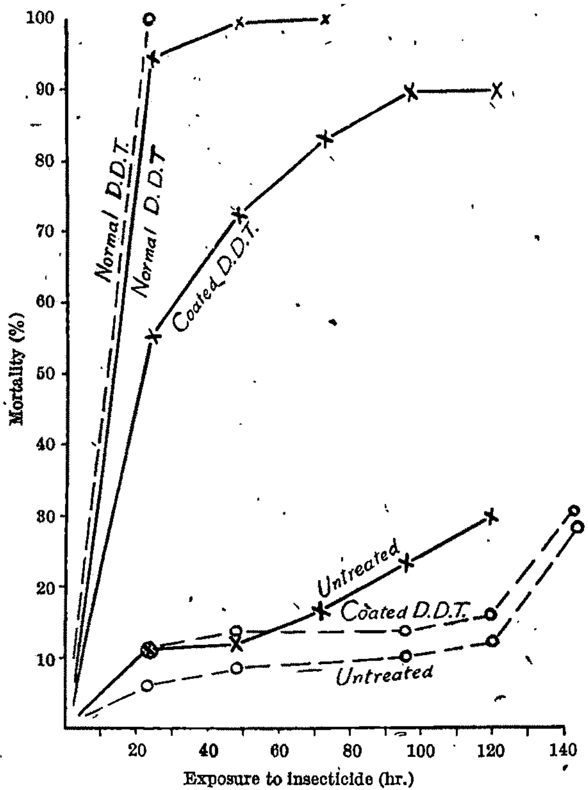
New Formulation of D.D.T. with Selective Properties

In order to produce insecticides which would be toxic only to certain groups of insects and not to others, it seemed a promising line of approach to make use of the known differences in the digestive capability of different insects. If individual particles of toxic compounds could be coated with substances digestible only by certain insects, then obviously only those insects would be killed by such coated insecticides.

Phytophagous insects are able to deal with hemicelluloses found in plant cell walls, and some wood-boring species also with celluloses, while carnivorous insects and insects such as most flies, bees and parasitic Hymenoptera cannot do so. Formulations of D.D.T. were therefore prepared in which the individual particles of D.D.T. were coated with degraded cellulose, by an acid precipitation of the degraded cellulose from alkaline solution to which a D.D.T. suspension had been added. A hardening process, carried out after acidification, greatly improved the characteristics of the coating.

These preparations were then sprayed on leaves or other surfaces and, after drying, test insects were allowed to come into contact with them. These tests showed that a thorough coating had eliminated the contact action of the D.D.T.

Comparing residual films of coated D.D.T. (sample *DC.* 103) and standard D.D.T. suspension both at 0·0157 mgm. D.D.T. per square centimetre, it was found that, in the former, the following D.D.T.-susceptible insects were not killed, or their mortality was significantly reduced: Diptera: *Lucilia sericata* Meig. (adults), *Syrphus* spp. (adults); Hymenoptera: *Apanteles glomeratus* Linn., *Apis mellifera* Linn., *Mormoniella vitripennis* Wlk. The same material sprayed at approximately the same rate on leaves which were then fed to larvæ of *Pieris brassicæ* Linn., *P. rapæ* Linn., and *Tortrix pronubana* Hübn., gave mortalities approaching those obtained with normal (uncoated) D.D.T. suspensions. Examples of the type of result obtained are shown in the accompanying diagram.



EFFECT ON *Pieris brassicæ* LARVÆ (—x—) AND ON *Lucilia sericata* ADULTS (– – o – –) OF 'COATED' AND UNTREATED D.D.T.

These experiments demonstrated that even the notoriously indiscriminate insecticide D.D.T. can be used as a selective insecticide specific to phytophagous insects. This development should prove useful in avoiding certain undesirable repercussions of D.D.T. spraying which are of considerable economic importance, such as outbreaks of other species of insects hitherto controlled by their natural enemies, for example, red spiders and mealy bugs after D.D.T. spraying of deciduous fruit against codling moth, and citrus against scale insect; or the rapid rebuilding of infestations of pests which are controlled by D.D.T. but are able to re-establish themselves because, in accordance with Volterra's Law of the Destruction of Averages, the simultaneous destruction of their natural enemies at the same rate as the destruction of the pests themselves leads to a more rapid building up of the pest population.

Dependence of Anomaloscope Matching on Viewing-Distance or Field-Size

In a recent communication bearing the above title[1], we pointed out that with a particular anomaloscope the R/G ratio in the mixture required to match a narrow-band yellow depended on the viewing distance. Further work on more than forty normal observers has confirmed this effect, and also established the fact that the effect for each observer is substantially the same whether one eye is used or two eyes, as in the original investigation. Most observers required more green in the mixture the greater the viewing distance. Taking the R/G ratio as unity for an observer viewing an 18-mm. field at 50 cm. (subtending 2°), the ratio drops at a decreasing rate to an average value of about 0·85 at 300 cm. (20 ft.), beyond which there is little further change. The spread of results for different individuals is considerable, some observers dropping below 0·6.

We have now found that the introduction of a 3-mm. artificial pupil in front of the eye tends to reduce the lowering in R/G ratio, especially for those observers showing a particularly large drop. Thus, one of us (R. G. H.) finds that his R/G ratio, which normally drops to 0·6, only drops to 0·85 when using the artificial pupil, although at 50 cm. the ratio is unity in each case. A 3-mm. opaque stop, on the other hand, necessitates an even lower ratio for the match. Moreover, with the artificial pupil it appears that the R/G ratio is dependent simply on the angle subtended by the field both for changes in field-diameter and viewing-distance, whereas with the natural pupil this is not so. This would indicate that part of the effect (in particular for those observers showing a large effect) is due to aberrations of the eye lens.

It may be that the effect would disappear if the chromatic aberrations of the eye were corrected, or possibly the explanation may involve the Stiles–Crawford effect.

Our thanks are due to Mr. D. W. O. Heddle for assistance with the observations.

Mr. E. Westlake and the Geology of the Cantal Region, Central France

Information is sought as to the whereabouts of a paper on the geology of the Miocene–Pliocene gravels of the Cantal region of central France which was prepared by the late Mr. E. Westlake of Fordingbridge.

Mr. Westlake stayed for six months at Puy Boudieu in 1905, and accumulated many hundreds of the pieces of flaked chert, which in form and type of flaking closely resemble the specimens from the basement beds of the East Anglian Crag sands, and of the stone beds resting on the chalk beneath the Forest Bed and glacial deposits of the north Norfolk coast. The collection was studied at Oxford by the late Prof. W. J. Sollas, who referred to it in the third edition of his "Ancient Hunters". Owing to his death before the publication of a detailed account and analysis of the collection, the specimens were transferred to the Ipswich Museum, where the late Mr. J. Reid Moir undertook to produce a paper on them. This was written before Mr. Moir's death, and it is hoped now to secure its publication. The collection is available for study at the Ipswich Museum.

As many of the specimens bear the late Mr. Westlake's notes as to site and depth at which they were obtained, and it is clear that they were *in situ* finds, it is most important that the record of the observations made on the beds should be recovered. As it is known Mr. Moir had the MS. in his possession prior to his death, and as it cannot now be found among his papers, it is supposed he may have sent it or lent it to someone to read. Anyone who has any knowledge of its whereabouts, or has access to the papers of the late Prof. Sollas, or to any other likely source where it might possibly be, is asked to communicate at once with one of the undersigned.

It is also known that drawings were prepared for the illustration of Mr. Moir's paper, and these are likewise missing. Any information about them would be valued.

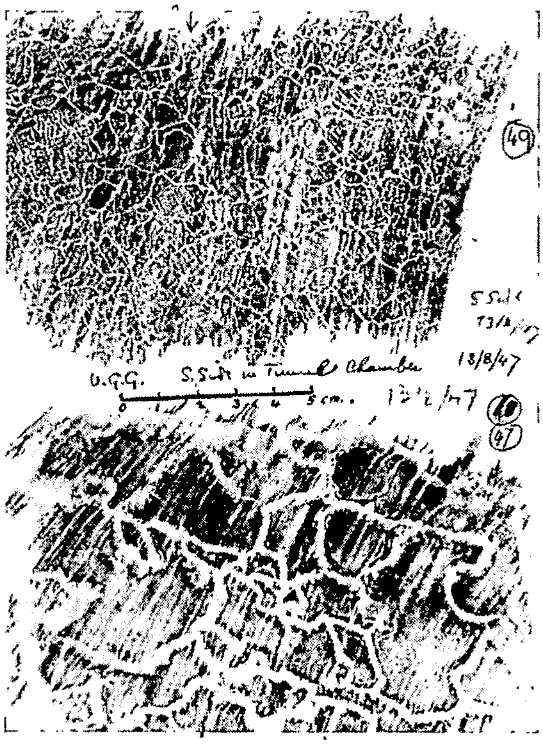
Growth of Glacier Crystals

The mechanism of the growth of the ice crystal in glaciers is one of the most important of the unsolved problems of glacier physics. Its solution may also prove of value in sciences other than glaciology.

As a preliminary to an investigation into the causes of crystal growth, I spent some months in the Alps last summer making a statistical survey of the crystal sizes at the ends of a number of glaciers. Surprisingly enough, these are the only records which are known to exist. They brought to light several interesting facts, the chief of which are: (*a*) that the crystals in *flowing* ice are not nearly so large as had often been reported; (*b*) that under certain conditions they are surprisingly small; and (*c*) that there seems to be some relationship between crystal size and the inclination of the glacier bed.



Rubbings of crystals in the Upper Grindelwald Glacier

Obviously these tentative deductions need confirmation in other glaciers, and this note is written in the hope that observations may be started in as many widely separated regions as possible. Investigations adequate for preliminary purposes are very simple. The process of recording ice crystal sizes consists of making rubbings with a pencil on paper. Under favourable conditions a single sample can be recorded in ten minutes, and the process need seldom take more than half an hour.

I should be pleased if exploration parties or private investigators who are willing to co-operate, especially those visiting glaciers other than those of the Swiss Alps, would communicate with me, so that I can provide detailed instructions for making rubbings and for the compilation of the data necessary for the analysis of the results.

DISINTEGRATION OF HIGHLY EXCITED NUCLEI

By D. H. PERKINS

Department of Physics, Imperial College of Science and Technology, London

IN a previous note[1], it was shown that most of the energy spectrum of protons ejected in nuclear disintegration stars produced in photographic emulsion by cosmic radiation could be explained in a general way by a simple evaporation process. We have now made detailed measurements on the angular distributions of the emitted particles, and compared them with what one would expect from the evaporation model of the nucleus.

Our data were obtained from twenty-four stars, each involving the emission of between fifteen and twenty-two charged particles from nuclei of silver, bromine and iodine present in the emulsion. These stars, which correspond to excitation energies of the same order of magnitude as the nuclear binding energies, represent about 2 per cent of the total observed in our plates, which were exposed for periods of forty days at altitudes of 3,500 m. and 4,400 m. at L'Aiguille du Midi, Chamonix.

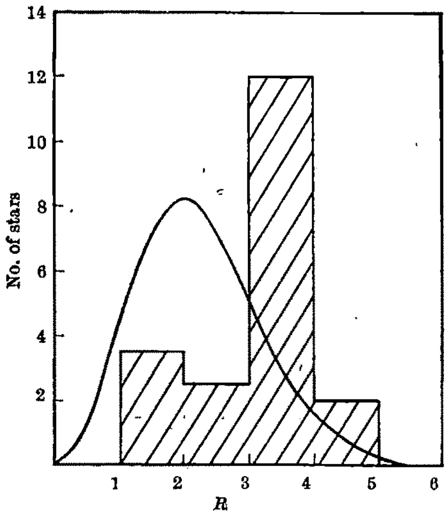

Fig. 1a

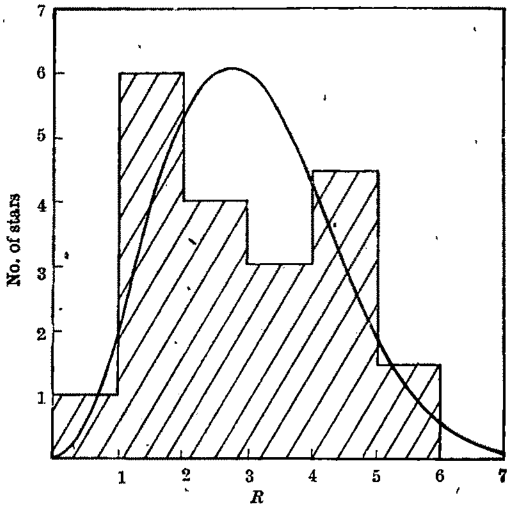

Fig. 1b

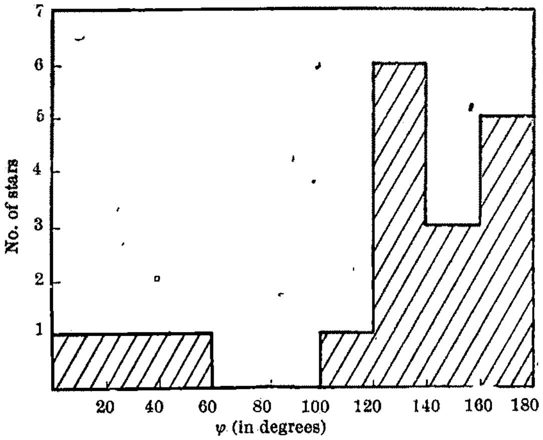

Fig. 2a

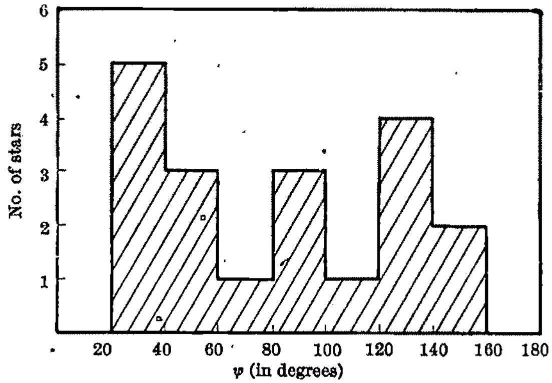

Fig. 2b

If the disintegration of a nucleus can be represented as a simple evaporation process, the angular distribution of the star particles should be, on the average, spherically symmetrical. Thus, if to each track is ascribed a vector of unit length, then the resultant of all the vectors of the star should have a scalar magnitude *R*, the probability distribution of which is determined by the random-walk theory[2]. The complete orientation of all tracks was determined by means of a goniometer eyepiece and by depth measurements in the emulsion, and a value of *R* calculated for each star. In determining the angular distributions we distinguish between the tracks of protons, alpha-particles and heavier nuclei, and the very heavy 'recoil fragments'; the latter are characterized by their short, heavily ionized tracks, which frequently show considerable Coulomb scattering owing to their high charge. In Fig. 1*a* the histogram shows the distribution of *R* for alpha-particles only; in (*b*) that for protons only. A comparison of the histogram with the random-walk curve shows that the alpha-particles have angular distributions with large deviations from spherical symmetry (the probability that the histogram corresponds to spherical symmetry is less than 10^{-4} from the χ^2 test). On the other hand, the protons are seen to be emitted almost isotropically.

Here it must be pointed out that the observed asymmetry cannot be due to the momentum transfer from the incident particle. Even the most energetic stars entail an excitation of only 1,000 MeV. Thus the velocity imparted to the whole silver nucleus by, say, an incident neutron would be $\leqslant 0 \cdot 01$ c., which is very small compared with that of each ejected particle ($\sim 0{\cdot}2$ c.). Furthermore, the sums of the components of R over all the stars, in horizontal and vertical directions respectively, show no essential difference.

In order to determine whether the alpha-particles are collimated in any special direction, we have calculated, for each star, the angle ψ between the short recoil fragment (or fragments) and the resultant direction of the alpha-particles. The distribution of ψ over all stars with observable recoil fragments is indicated in Fig. 2*a*. The alpha-particles show a strong tendency to be ejected in a direction opposite to that of the recoil fragment. On the other hand, as might be expected, the protons do not appear to show any such directional effects (Fig. 2*b*).

A possible explanation of the collimation of the alpha-particles and heavier sub-nuclei is that the first stage in the disintegration process consists of the breaking up of the nucleus into two or more heavy fragments. Each may be supposed to have considerable momentum, and we must further assume the fragments to be of different sizes, and the excitation energy to be asymmetrically divided between them. We then postulate that the lighter fragments, which must necessarily carry most of the kinetic energy, break up spontaneously, preferentially into stable particles with low internal energy, such as alpha-particles, but possibly also a few protons and neutrons. The heavy 'recoil fragment', on the other hand, retains most of the original excitation energy as internal energy, and then 'cools down' by evaporating off neutrons and protons (and, of course, a few alpha-particles). The angular distribution of the protons would then be more or less isotropic, as observed. From the charge carried away by the alpha-particles and protons, it is possible to estimate that on the recoil fragments. We find that their ranges are roughly in agreement with what one would expect, if their momenta were equal and opposite to that of the alpha-particles.

If the above hypothesis is true, one would not expect the energy distribution of the alpha-particles to conform to evaporation theory. In actual fact, measurements on the ranges of the alpha-particles yield an energy spectrum which appears to be much broader than could correspond to an evaporation process. However, it will be necessary to improve the statistical accuracy of our data in order to confirm this.

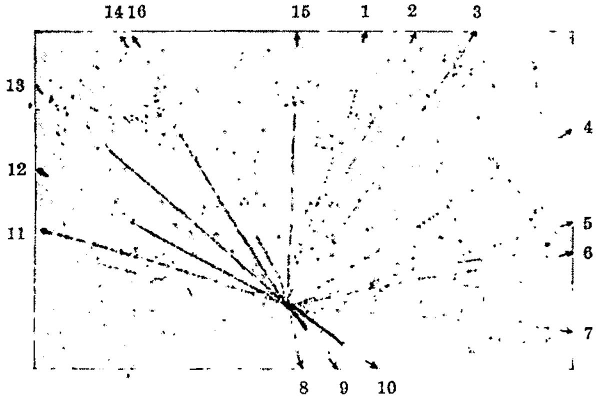

Fig. 3. DISINTEGRATION OF SILVER OR BROMINE NUCLEUS IN ILFORD *B*2 EMULSION, IN WHICH BOTH THE ALPHA-PARTICLES (11–15) AND PROTONS (1–8) ARE STRONGLY COLLIMATED. PARTICLE 16 ENDS IN THE EMULSION AND IS PROBABLY A VERY SLOW MESON. TRACKS 9 AND 10 ARE THOSE OF HEAVY RECOIL FRAGMENTS

It must also be emphasized that not all our disintegrations conform to the above scheme. In a few cases no recoil fragment is visible, and in one extreme example (Fig. 3) the protons as well as the alpha-particles show strong collimation.

The excitation energy required in the processes we have described is estimated at 500–1,000 MeV. Now, the great majority of stars produced by 200 MeV. deuterons and 400 MeV. alpha-particles from the Berkeley cyclotron show forks with only three or four charged particles; no large stars have been reported[3]. As explained by Serber[4], this is because the nuclei become partly transparent to the incident nucleons with these energies. In a similar way, a σ-meson, when captured into a nucleus, would appear to undergo annihilation by interaction with a single nucleon, which is excited to an energy $\sim$ 200 MeV. This nucleon will then leave the nucleus after only one or two collisions, with an energy loss of only some tens of million electron volts. Thus our own observations, and those of Dr. Powell and co-workers[5], show that stars produced by σ-meson capture generally involve only two or three charged particles. Very rarely are more than four secondaries produced. These two experimental facts indicate that it is unlikely that the energetic stars can be explained by nuclear capture of, for example, neutrons with energies of a few hundred million electron volts, or nuclear capture and annihilation of neutral or fast charged mesons with the usual values of mass. Probably, therefore, the stars described above are the results of another process, for example, the inelastic scattering of very fast cosmic-ray particles, with energies in the relativistic region where the cross-section for scattering on nucleons becomes large.

It is hoped to publish a fuller account of this work in the near future.

RELATIONSHIPS OF VAPOUR PRESSURE, CAPILLARITY AND TEMPERATURE IN CLAYS

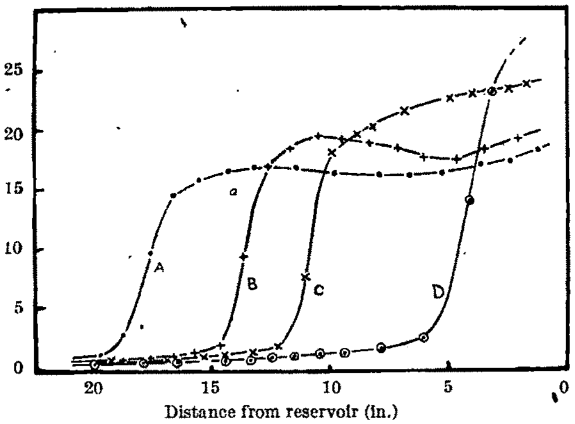
By B. VASSILIOU and DR. J. WHITE

Department of Refractory Materials, University of Sheffield

WHEN columns of a commercial kaolin ('Supreme Kaolin') of uniform moisture content are placed in sealed, vertical tubes, along which a constant temperature gradient is maintained, and having a reservoir of water at constant temperature at their lower, cool ends out of contact with the clay, 'stepped' moisture distribution curves of the type shown in the accompanying diagram are obtained, the step moving progressively, but with decreasing velocity, towards the cool end of the tube with increasing time.

It has been found that the observed distributions can be accounted for in terms of the relation

$$\log_{10}P = -\frac{2252}{T} + 7{\cdot}92 - \frac{2{\cdot}146 \times 10^{-5}}{rT} + \frac{2{\cdot}677 \times 10^{-8}}{r} - \frac{1{\cdot}258 \times 10^{-3}}{T}(P_0 - P), \quad (1)$$



MOISTURE DISTRIBUTION IN CLAY COLUMNS UNDER A TEMPERATURE GRADIENT

	Initial water	Time (hr.)
A	16·0	35
B	16·0	125
C	17·8	288
D	17·8	1013

if the vapour pressure is assumed constant from the position of the inflexion near the top of the step to the hot end of the column. This equation was derived from the ordinary vapour-pressure/capillary-radius relation using the approximate substitutions

$$\gamma = 114{\cdot}4 - 0{\cdot}1425\, T$$

$$\text{and } \log_{10} P_0 = -\frac{2252}{T} + 7{\cdot}92,$$

P being the vapour pressure in cm. of mercury in a capillary of radius r cm. at $T°$ abs., P_0 the vapour pressure over a plane water surface at the same temperature and γ the surface tension in dynes/cm. Over the range of vapour pressures involved, the last term on the right-hand side of equation (1) could be neglected. Since earlier work had shown that lowering of the vapour pressure was negligible with this clay at more than 3–4 per cent water, P could be taken as that of a plane water surface at the temperature of the inflexion. Using the appropriate values of P, r was calculated for various positions of known temperature along the column, the curves obtained being of similar form to those reproduced, except that the moisture variation was expressed in terms of r instead of actual moisture contents. By direct comparison of calculated r values with the moisture contents on corresponding curves, the expression

$$r \times 10^7 = 2{\cdot}0\, W^{1{\cdot}57}, \tag{2}$$

where r is the effective capillary radius in cm., and W the weight percentage of water has been derived. Applied to the calculated data, this expression gives an excellent fit with the curves shown and also with curves obtained when the whole of the column had come to equilibrium with the reservoir.

Some light on the underlying rate-mechanism has been obtained from experiments in which water alone or a clay–water mixture was placed in trays evenly spaced along the tubes (equivalent to using a broken column). Movement of water could then take place only by an evaporation–condensation mechanism via the narrow annular spaces round the trays. On plotting the moisture contents of the trays against their position in the tube at various times, curves similar in form to those shown were obtained.

With water alone, the evaporation-rate from each tray was constant until it was dry, the rate varying from tray to tray as a linear function of the vapour pressure. Of the moisture evaporating from any tray, approximately one half condensed in the first tray below, one quarter in the second and one eighth in the third, the remainder passing apparently direct to the reservoir, as no condensation on the tube was found. The movement of the step from the fourth tray onwards is, therefore, given by the equation

$$t_n = cW \times 1{\cdot}20 \times 10^{-8} \left[\frac{5}{12}n + \frac{61}{72} - \frac{2}{9}\left(-\frac{1}{2}\right)^n\right] \exp 5190/T_n, \tag{3}$$

t_n being the time in hours for the nth tray at T_n to become dry, W the initial weight of water in each tray and c a constant equal to 1870. A similar type of equation can be made to fit the movement of the step on the curves shown, and it would appear that movement of the water is an activated process (evaporation–condensation or activated diffusion) involving water which is 'bound' to the clay particles. At higher moisture contents where free flow is possible (necessitating horizontal tubes) no 'stepped' distribution is developed until the moisture content has been reduced by drying.

With a clay–water mixture in the trays, similar relationships hold except that the evaporation-rate for each tray decreases rapidly at less than 3–4 per cent water due to lowering of the vapour pressure by capillarity. During this stage, the vapour pressure of any tray approaches equilibrium with that of the nearest tray still in its constant-rate period of drying at a vapour pressure sensibly that of a plane water surface. From the drying curves it has, therefore, been possible to determine the vapour pressure of the clay at various temperatures and water contents. From this data the expression

$$\Delta H - 10{,}300 = \frac{2350}{W - 0{\cdot}79} \tag{4}$$

has been derived, where ΔH is the total heat of evaporation in cal. per mol. of water when there are W gm. water per 100 gm. clay.

The form of the denominator in equation (4) implies a lower limit to capillarity at $W = 0{\cdot}79$. Equation (2), on the other hand, indicates a continuous rise of r with water content, slow at first, then rapid. Actually at more than 1 per cent water the data can be fitted reasonably by a straight line cutting the axis of zero r at approximately 0·79 per cent water. This value has been taken tentatively as indicating completion of a monomolecular adsorption layer on the clay surface, giving a value of the order of 300,000 sq. cm./gm. for this clay. On the same basis, Pembina bentonite, for which continuous column experiments yielded the relation

$$r \times 10^7 = 0{\cdot}00022\, W^{3{\cdot}3}, \tag{5}$$

requires 16–17 times as much water to complete the adsorption layer, giving a surface area of 4,800,000–5,100,000 sq. cm./gm. This is close to Schofield's estimate of 4,700,000 sq. cm./gm. for Wyoming bentonite[1], but the agreement may be only apparent as Pembina bentonite is non-swelling. The vapour pressure isotherms of the two clays calculated from (2) and (5) for 20° C. agree well with the observation that, stored in the laboratory, the kaolin picks up 0·9–1·0 per cent and the bentonite 16–17 per cent moisture.

A full account of the work will be published in due course. One of the authors (B. V.) acknowledges with gratitude the award of a British Council scholarship.

RELATION OF MANGANESE AND SOME OTHER METALS TO THE IRON STATUS OF PLANTS

By ERIC J. HEWITT
Long Ashton Research Station, Bristol

IT has been shown with plants growing in water culture that iron deficiency symptoms may be readily induced by excessive concentrations of manganous salts[1–6]. A reciprocal effect on the incidence of manganese deficiency in the presence of high concentrations of iron compounds has also been shown for soya bean[6] and some fruit crops[4]. These results have been interpreted[6] as suggesting that iron deficiency and manganese toxicity are but relative terms for the same disorder resulting from too wide Fe/Mn ratios, and that manganese deficiency and iron toxicity are similarly relative. It is generally assumed that metabolically active iron exists in plants in the ferrous state, and becomes inactive after oxidation to the ferric state. In one of the experiments referred to[6], this oxidation was assumed to follow reaction with manganese compounds previously oxidized to a higher valency state. A similar ability to induce iron deficiency was forecast for cobalt on account of its still higher oxidation-reduction potential than the manganese system postulated, and some indication was obtained that iron deficiency was induced more readily by cobalt salts.

In other experiments using sand or water culture, it has been shown that compounds of metals such as copper[7,8], zinc[5,7,9,10], and chromium[11,23] can also induce symptoms apparently identical with those of iron deficiency. Observations in the field[10,12,13,14,15] also confirm that similar symptoms may be induced in a variety of crop plants by toxic levels of compounds of copper or zinc in soil, and possibly by other metals in industrial sewage spread over land in which such crops are growing; similar effects may also appear in the vicinity of copper and zinc smelting works, and in areas where zinc-bearing dolomitic limestone occurs[15]. Naturally occurring compounds of cobalt or nickel may also cause this effect in acid soils[16]. It is thus evident that the compounds of several metals, in addition to manganese and cobalt, may induce iron deficiency. Furthermore, recent results obtained with several crop plants grown in sand culture[12,17,18] have shown that symptoms of manganese toxicity can be distinguished from those of manganese-induced iron deficiency and are readily produced even in the absence of the latter. It thus seems necessary to examine more fully the relation of the effects of 'toxic' concentrations of a number of metallic ions to iron metabolism and the appearance of the visual symptoms of this deficiency and of other injurious effects. Results are given below of some experiments made in sand culture with sugar beet, chosen because it shows readily symptoms of iron deficiency in the field in the presence of some of the metals mentioned, and is known to be remarkably tolerant to high concentrations of manganous ions[12].

Experimental. Young sugar beet seedlings were transplanted into purified sand[12] in 10-in. bitumen-painted clay pots[19], and the cultures arranged in two series according to two types of iron supply, as follows: Series 1: Purified sand only, with iron supplied as ferric citrate at 0·1 milli-equiv. per litre in the complete nutrient solution. Series 2: Purified sand mixed with magnetite at the rate of 100 p.p.m., but no iron added in the nutrient solution. In both series the ions Pb^{++}, Zn^{++}, Cu^{++}, Co^{++}, Ni^{++}, Mn^{++}, Cr^{+++} and CrO_4'' (the last to supply the same weight of chromium as the Cr^{+++}) were added separately, at concentrations of 0·5 and 1·0 milli-equiv. per litre in the nutrient solution. There were also three control treatments without any of these additions, and in which iron was supplied as above, either as magnetite, or as ferric citrate, or was omitted altogether.

Plants in the control treatment where iron was omitted developed acute symptoms of chlorosis and also some brown intervenal necrosis typical of iron deficiency. Control plants given iron, either as citrate or as magnetite, grew vigorously and the foliage was normal. Chlorosis of younger leaves, typical of iron deficiency, developed in all plants given the additional ions listed above, and ranged from very severe (total yellow) to a trace. The severity of chlorosis was observed to be in the order of

$$Co^{++} > Cu^{++} > Zn^{++} = CrO_4'' > Ni^{++} > Cr^{+++} > Mn^{++} > Pb^{++};$$

that of the controls where iron was omitted was similar to plants given extra Zn^{++} or CrO_4''. This same order was shown in both the citrate and magnetite series, although certain broad differences were noted between the two series. Thus in the citrate series, the chlorosis caused by the chromic or manganous ions, and the differential effect of using two concentrations, were more marked. The effects of copper, zinc or chromate respectively were comparable in the two series, but cobalt and nickel produced more severe injury in the magnetite series than with citrate. Evidence was obtained, by painting the leaf surface with 0·25 per cent ferrous sulphate solution plus a wetting agent, that the chlorosis was *in all cases* due to failure in the iron metabolism. A response was evident in about forty-eight hours, and complete recovery of the treated areas occurred in five days, while untreated leaves, including the younger ones, remained chlorotic.

In addition to the induced chlorosis, other apparently direct toxic effects were noted in the Co^{++}, Ni^{++}, Zn^{++}, Cu^{++} and CrO_4'' treatments; here the plants were considerably dwarfed, whereas those given Cr^{+++}, Mn^{++} or Pb^{++} grew with normal vigour. Brown intervenal necrosis usually developed in the chlorotic leaves, including those of control plants lacking iron. This necrosis ranged from very severe with cobalt or nickel, to slight or nil with chromium as sulphate, manganese or lead. In the presence of nickel the necrosis appeared rapidly and frequently preceded marked chlorosis, and, when cobalt was given, both necrosis and chlorosis were quick to appear. The necrosis was unusually dark brown or even black in colour in these two latter treatments, and eventually resulted in complete blackening and death of the young leaves and of the plants. Fading, tinting and necrosis also developed in the older leaves of plants given zinc, cobalt or nickel, the last element in particular producing an orange tinting of the faded older leaves. These symptoms were all distinct from those identified as resulting from iron deficiency. A similar distinction has been noted for flax suffering from zinc toxicity[10]. The general order of toxicity, as distinct from induced chlorosis, was as follows:

$$Ni^{++} > Co^{++} \gg Zn^{++} > Cu^{++} > CrO_4'' \gg Cr^{+++} = Mn^{++} \text{ and } Pb^{++}.$$

As previously stated, sugar beet has been found to be relatively tolerant to high concentrations of manganous salts. Symptoms of manganese toxicity distinct from and without those of iron deficiency, however, were produced in another experiment in the *older leaves* of plants given 6 milli-equiv. per litre of manganese in the presence of an adequate iron supply[12]. These observations have confirmed previous conclusions that manganese toxicity and manganese-induced iron deficiency are distinct effects[15,17].

Symptoms which appeared in some of the older leaves of the plants given extra zinc resembled the effects of manganese deficiency and occurred simultaneously with iron-deficiency symptoms in the young leaves of the same plant. Determinations of soluble manganese[20] showed that the affected leaves yielded less than 0·015 and 0·005 p.p.m. of manganese in the tissue extract when given 0·5 and 1·0 milli-equiv. per litre Zn^{++} respectively, as compared with 0·05 p.p.m. in leaves from the control (ferric citrate only) plants. The simultaneous deficiency of iron and manganese in the same plant was observed in another experiment[13] with oat plants grown in sand cultures from which both elements were omitted. In this latter instance, typical iron-deficiency chlorosis and 'grey speck' could be distinguished on the same leaves, and a similar condition was identified in the field in 1946 and 1947, where liming had been used in an attempt to control injury by industrial sewage[12]. Specific morphological effects ascribed to the simultaneous deficiency of these elements have also been described for leaves of *Theobroma cacao*[21].

Discussion. The suggestion that oxidation-reduction reactions may be responsible for the iron-deficiency chlorosis induced by manganese and cobalt may be considered on the basis of this new evidence. It is clear that manganese and cobalt are in no way unique in their capacity to induce such chlorosis and that, of the metals examined, at least one, namely zinc, does not undergo valency changes associated with simple oxidation-reduction reactions; of the others, manganese was one of the least active, while copper and cobalt were the most active in producing chlorosis. These results bear no relation to the E_0 values given by Latimer[22] for changes in valency of the *simple ions*. Thus the E_0 values for $Co^{++} \rightarrow Co^{+++}$, $Cu^{+} \rightarrow Cu^{++}$ and $Mn^{++} \rightarrow Mn^{+++}$ are $-1·84$, $-0·167$ and $-1·51$ V. respectively, whereas for $Fe^{++} \rightarrow Fe^{+++}$, $E_0 = -0·77$ V. Thus copper, even as the cupric ion, should, on that theory at least, be incapable of converting the ferrous to the ferric ion; while it must be assumed that, as the cobalt and manganese were given in the reduced valency form, they must first have been oxidized in the plant to a higher valency by reactions that, in the absence of these metals, do not influence the ferrous-ferric equilibrium. Furthermore, the existence of some of the high-valency metallic ions in living plants is doubtful. Nickel, for example, caused chlorosis, but tetravalent nickel exists only as NiO_2 under strongly alkaline conditions, and the cobaltic ion can attack water.

On the other hand, many of the metals studied would exist as complex ions in the plant. The oxidation-reduction potentials of complex ions, however, may often differ greatly from those of the simple ions. For example, for

$$Co(NH_2)_6^{++} = Co(NH_2)_6^{+++} + e^-, E_0 = -0·1 \text{ V.},$$

while for the $Fe^{++} \rightarrow Fe^{+++}$ change when iron is present as a complex with *o*-phenanthrolene, $E_0 = -1·14$ V. Thus it is clear that explanation of the observed facts must await more accurate information on the form of combination of the metals involved and on their metabolism.

A suggestion that active iron in plant tissues may be closely associated with certain protein fractions[1] requires that the possible influence of various metals on the precipitation, denaturization, or adsorptive properties of such protein fractions should also be borne in mind. Competition between the toxic metal ions and iron in enzyme systems involved in chlorophyll formation, or the activation of enzyme systems influencing the ferrous-ferric iron equilibrium may also be important in reactions inducing symptoms of iron deficiency. It is not, however, justifiable at this stage to infer that the mechanism causing chlorosis is analogous in each case. Thus data showing increased iron accumulation in the presence of toxic concentrations of zinc[10,15] would seem to exclude simple antagonism as a cause of chlorosis in some instances, while the differential response to Cr^{+++} and Mn^{++} in the presence of magnetite or ferric citrate suggests that antagonism may still be significant in others, and work on copper-induced chlorosis[8] suggests that two separate effects may be involved.

Conclusions. The evidence considered here points to the following conclusions: (1) Manganese is not unique in its ability to induce iron-deficiency symptoms, and may, in fact, be less active in this respect than many other metals. (2) The existence of the simultaneous deficiencies of iron and manganese in the same plant has been observed in a number of independent instances, which suggests that these elements have some independent functions in plant metabolism. (3) Toxic effects of excess manganese can be readily distinguished from symptoms of iron deficiency; again suggesting independent effects of these elements. (4) Hypotheses based on oxidation-reduction potentials of *simple ions* appear inadequate to explain the activity of the metals considered herein in inducing iron deficiency, and more than one mechanism may be involved.

NATIONAL RESEARCH COUNCIL OF CANADA

ANNUAL REPORT

THE thirtieth annual report of the National Research Council of Canada, 1946–47, includes the report of the president, Dr. C. J. Mackenzie, together with the financial statement for the year ended March 31, 1947 (Ottawa: National Research Council). Dr. Mackenzie's report gives a general conspectus of the work of the Council, but for scientific workers and others interested in details of the projects in progress, a more comprehensive booklet, "The National Research Council Review for 1946", is available on order from the Council. At the end of the War, a Defence Research Organisation was formed under the Department of National Defence, and is responsible for determining what research is to be done for military purposes during peace-time. The president of the Research Council is *ex officio* a member of this Board. Associate committees with purely war-time functions which had completed their assigned tasks have now been disbanded, but at the end of 1946 there were thirty-three active committees. Eighty-one research grants were made in 1946–47 directly by the Council, 82 through the Division of Medical Research and 93 through committees, while scholarships were awarded to 185 graduate students to enable them to extend their training in research.

Conversion of the Council's activities from war to peace was completed during the year, but the Council is at present recruiting the personnel required to bring its peace-time establishment to full strength. An Atomic Energy Research Division has been established at Chalk River to investigate the applications of atomic energy and the use of its products in industry and medicine. The Council took over on February 1, 1947, full responsibility for the administration and operation of atomic energy development at Chalk River, and will carry on these activities in accordance with broad general policies fixed from time to time by the Atomic Energy Control Board. A Division of Medical Research has been organised to stimulate and support investigations in this field, and has set up, at the request of the manufacturers, a committee to advise on the distribution of streptomycin and to make recommendations as to clinical conditions for which streptomycin might be used. A Building Research Division is being established, and work is progressing on the construction of a Prairie Regional Laboratory at Sasketoon for the promotion of studies on the better utilization of agricultural surpluses, notably wheat, and farm waste products such as straw. The newly established Division of Information Services has substantially expanded its survey of German and other reports for the solution of specific manufacturing problems.

An Electrical Engineering and Radio Branch has been created to co-ordinate and direct work in this field. The most important contribution in the development of radio aids to air and marine navigation during the year was a radar distance indicator, which enables an aircraft pilot to ascertain his distance from one or more pre-selected ground stations, its distance being read directly in miles on a simple meter. The Council is also co-operating in the development of radar equipment, by means of which it is hoped to determine base lines up to 300 miles long with an accuracy of 20 ft., and to permit spot fixes of photographic aircraft with an accuracy of 100 ft. in 200 miles. The laboratory is also engaged in developing a radio altimeter capable of providing a continuously recorded altitude measurement accurate within 50 ft. In the Division of Physics and Electrical Engineering, work has been undertaken to provide first-class facilities for scientific standardization, and a new project with a magnetic airborne detector is directed to the scientific determination from the air of the earth's magnetic elements and the location of mineral and oil deposits. Two experimental buildings of the radiant-heating project have been constructed, and work has been resumed on the thermostatic control of heated refrigerator cars. An infra-red detector was used successfully to ascertain whether joints were heating on transmission lines, and an apparatus has been completed by means of which the thermal conductivity of metals can be measured up to 800°.

A programme of photographic research is under way to determine the important factors in making positive prints on paper so that the maximum amount of information can be recovered from the negative, and a paper describing the final techniques developed for night photography is being published. Studies have been made of the factors affecting the dimensional stability of film under actual survey conditions, and further work has been done on the measurement of emulsion speed for aerial photography by a resolving power criterion, as well as on photometric standardization. Work in colorimetry has been initiated, and the Canadian Photographic Research Committee has been replaced by an Associate Committee on Photographic Research.

In the Division of Applied Biology one group is primarily concerned with fats and oils, and work on the processing and treatment of domestic oils for edible purposes has continued, particularly attempts to obtain an edible fraction from linseed oil and another fraction with superior properties for use in the paint industry. Work has continued on egg products, pork products and dairy products, particularly butter and dried milk. Preliminary trials of a Fritz butter-making machine from Germany indicated that the difficulties in meeting Canadian standards can be overcome. Efforts are being made to improve the versatility of chemical methods of assaying for riboflavin, thiamin and niacin. In the Ottawa laboratories, pilot plant studies on the production of *l*-2 : 3-butylene glycol from wheat with *Aerobacillus polymyxa* were completed, and fermentation efficiencies of 90–100 per cent were consistently attained. A method has been developed for the manufacture of phthalate resin from 2 : 3-butylene glycol and phthalic anhydride which has outstanding physical properties and is of interest to paint manufacturers. Wheat syrup was investigated on a semi-pilot plant scale, and first-quality corn syrups were prepared from the starch separated.

The reorganisation of the Division of Chemistry into Fundamental Chemistry and Chemical Engineering was completed, and the organic section of the former branch has investigated synthetic rubber and the isolation of new alkaloids. Many studies of photosensitized reactions have been made, including investigations of free radical processes by the mirror technique. Studies in surface chemistry have included the effect of physical adsorption on the electrical conductivity of activated carbon rods; but the work of the inorganic section, like that of the chemical engineering branch, has been concerned with the atomic energy project. The textile section has carried out further work on the rot-proofing of textiles, thermal insulation of protective clothing, the use of synthetic detergents, water-repellants and moth-proofing agents. The corrosion of steel by water is being studied under static and under flow conditions, including the mechanism of corrosion inhibitors. Preliminary data have been obtained on a new type of catalyst for the oxidation of ethylene to ethylene oxide, and an extensive research has been continued on the chemistry of long-chain unsaturated fatty acids. Further work on a new type of propeller de-icing, on the control of frost on standing aircraft, the development of an effective rain repellant for aircraft windows and of a catalyst for the oxidation of carbon monoxide to permit accurate determination of low concentrations in air, promise important peace-time applications. The relation between chemical structure and plasticizer reaction is being studied, while in the aeronautical laboratories the tailless glider was one of the major projects. The hydraulics laboratory completed tests on a model of a Great Lakes' harbour to determine the effect of a proposed pier extension upon sand-bar formation in the harbour entrance. Research on low-temperature lubricants has yielded much valuable information on flow characteristics of greases at low temperatures. Work on artificial limbs has continued in the structures laboratory, making use of processes developed during research on moulded aircraft components. Problems involved in 'panel', or radiant, heating are being investigated, and an important advance in low-cost housing was made in the development of a modular system for the construction of pre-fabricated houses.

BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION

ANNUAL REPORT

THE work of the British Electrical and Allied Industries Research Association throughout the year ended on September 30, 1947, is recorded in the twenty-seventh annual report recently issued.

The field of activity of the Association is perhaps most readily appreciated from a block diagram given in the report, in which twenty-two main lines of research are represented, several of which divide into as many as ten distinct branches. These include extensive studies of insulating and magnetic materials and of gaseous discharge phenomena, in regard to which researches of both a fundamental and of an applied character are in progress. Surge phenomena, communication interference, earthing safety and circuit problems, overhead lines, power plant and rural electrification are also main subjects of investigation.

In the section on heating, cooking and allied problems, reference is made to work in progress on a heat pump installation and to the early publication of a final report on an experimental investigation of the thermal characteristics of a concrete floor heated by buried cables. In connexion with the work on surge phenomena it is reported that a recurrent surge oscillograph has been developed which employs a sealed-off tube and gives a performance comparable with that obtained with the continuously evacuated type of instrument. Integrating electricity meters provide the subjects of several extensive investigations. A number of these is concerned with the behaviour of instrument jewels, the initiation of a new series of tests on tungsten/diamond and tungsten/sapphire bearings being reported. A detailed examination of the parasitic forces occurring in induction-type watt-hour meters has also been made.

It is interesting to note the wide range of researches supported by the Association in various university departments throughout Britain. These include investigations on the properties of high-pressure, high-temperature steam, work on the fundamental properties of magnetic materials and on the improvement of electrical sheet steels. Studies on the development of spark discharges include an investigation of the build-up of ionization by the Wilson cloud-chamber technique, and work on the high-frequency corona discharge. Experiments on the use of artificial illumination in horticulture are also being conducted in one university department.

In the introduction, the first paragraph deals with the reaction upon the Electrical Research Association of the transfer of the electrical supply industry in Britain to public ownership. The supply industry has provided some 30 per cent of the income of the Association, and the future relation of the British Electricity Authority with the Association is therefore of great importance. It is reported that the chairman of the Authority has confirmed the intention to support the Association and has provided for the safeguarding of the Association's finances during a transitional period in which the new basis will be worked out. The present report testifies to the existence within the electrical industry, both in the supply and the manufacturing spheres, of a spirit of co-operation in research which has built up, by good will and patient effort, a powerful instrument for the scientific and technical advancement of the industry as a whole. Such an achievement is a contribution, by no means inconsiderable, to the vital industrial needs of Great Britain at the present time.

J. G.

Rh NOMENCLATURE

FOLLOWING the hearing of evidence from interested persons, W. B. Castle, M. W. Wintrobe and L. H. Snyder have reported[1] to the Surgeon-General of the U.S. Public Health Service on the nomenclature of the anti-*Rh* typing sera. The report traces the history of *Rh* nomenclature, summarizes the evidence for and against Wiener's and Fisher's nomenclature respectively, and recommends that the Wiener nomenclature shall appear first on the label of serum containers, followed by the Fisher terminology in parentheses, thus: "Anti-Rh_0 (Anti-D)".

The authors have, on the whole, presented a fair and accurate summary of the complex history of the development of *Rh* theory and nomenclature, and of the associated controversies. They have, however, not pointed out that Fisher's notation was put forward[2] a year or more before any discussion of the possible genetic situations. Fisher's essential contribution lies in his postulation of three pairs of antigens, the antigens of each pair separately behaving as though they were the products of a pair of allelomorphic genes. Neither the validity nor the great convenience of Fisher's notation depends on the precise cytological basis of these facts. The most likely explanation consists in the existence of three very closely linked loci, but one cannot at present rule out the possibility of some such mechanism as that of a single gene with three side-chains each capable of variation. Even for this type of mechanism, Fisher's notation would give a more complete and convenient specification than that of Wiener. It should also be pointed out that Wiener's present nomenclature differs greatly from that originally put forward, and a claim of priority for it can scarcely be based on the fact that his original system was published before that of Fisher.

The compromise reached is an advance on previous American practice, and indirectly will do much to enable workers on the *Rh* factor in different parts of the world to understand one another's language. It is, however, to be regretted that Fisher's notation is relegated to parentheses; while its obvious advantages will ensure its use in research work, the first name on the label will tend to be perpetuated among clinical pathologists. A. E. MOURANT

PROPOSED INSTITUTE OF RECORDED SOUND

THE Association of Special Libraries and Information Bureaux has taken the initiative, in response to a large number of requests, of calling together representatives and individuals known to be interested in the formation of a permanent means of collecting, and making available to students and others, documentary and artistic material in the form of recorded sound. A meeting was therefore held on March 3 to discuss the matter, and to ascertain what is practicable now and in the near future.

Mr. Frank Howes (president of the Royal Musical Association), as chairman, gave an outline of the proposals already put forward in general terms, and the usefulness of such a potential organisation, started perhaps on the lines of the British Film Institute, was detailed by representatives of such important bodies as the British Museum, the British Council, the British Broadcasting Corporation (which uses sound recording on an immense scale in many forms), the National Register of Archives, the Scientific Film Association, the English Song and Folk Dance Society, the International Folk Music Council, departments of the University of London interested in languages, the commercial and private recording companies, the professional societies, and other individuals.

Mr. A. P. H. Saul described how collections of recorded material have been built up elsewhere, both on the Continent, especially Vienna, over the past fifty years, in Berlin and in the United States; but facilities are totally lacking in Great Britain. As a consequence valuable historical material is being lost, or at the best dispersed in private collections, of which no information is readily available. The interpretations of musicians, the voices of statesmen and poets, the remoter languages, the interesting cases of defective speech, and strange music of other lands are probably all available somewhere, but are denied to serious students of history, anthropology and phonetics.

Since practice is often better than mere precept, the value of such records was demonstrated most effectively by Mr. H. L. Fletcher, who played montage records, with comments, made that morning, from material received from a number of sources. Thus were reproduced the voices of Lloyd George, Asquith, James Joyce, Woodrow Wilson, Vesta Tilly (all pre-1914), Japanese music, an original 1660 pipe organ, a man of eighty recalling the original tune of "Brigg Fair", and modern poets. Also the voices of Gladstone, and, of course, all singers since 1900 are known to be available.

Questions of the copyright in reproductions for practical use, storage, finance, interchange with other countries, research and relations with other interested bodies were generally discussed. The meeting constituted itself a provisional council, having approved the idea that such an institute should go forward, and appointed a committee to study details and make a report.

With Mr. F. Howes as chairman the following were appointed to this exploratory committee: Mr. P. May (A.S.L.I.B.), Mr. A. P. H. Saul, Dr. D. B. Fry (Phonetics Department, University College, London), Mrs. J. Lancaster-Jones (British Council), Mr. D. Shawe-Taylor, Mr. A. C. Cameron (Educational Department, Electric and Musical Industries, Ltd.), Mr. H. L. Fletcher (Association of Professional Recording Studios) and Dr. L. E. C. Hughes (British Sound Recording Association).

FORTHCOMING EVENTS

*(Meeting marked with an asterisk * is open to the public)*

Tuesday, March 30

MANCHESTER GEOGRAPHICAL SOCIETY (in the Geographical Hall, St. Mary's Parsonage, Manchester), at 6.30 p.m.—Mr. H. E. Faulkner: "The East India Company".

SOCIETY OF INSTRUMENT TECHNOLOGY (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 6.30 p.m.—Mr. S. S. Carlisle and Mr. B. O. Smith: "An Experimental Electrical Pressure Meter for Measurement of Furnace Roof Differential Pressures".

ROYAL PHOTOGRAPHIC SOCIETY, SCIENTIFIC AND TECHNICAL GROUP (at 16 Prince's Gate, London, S.W.7), at 7 p.m.—Symposium on "Modern Techniques in Stereoscopy and their Applications".

Wednesday, March 31

MANCHESTER LITERARY and PHILOSOPHICAL SOCIETY, SOCIAL PHILOSOPHY SECTION (in the Portico Library, 57 Mosley Street, Manchester), at 5.30 p.m.—Mr. N. S. Hubbard: "The Place of Philosophy in Christian Civilization".*

BRITISH INSTITUTION OF RADIO ENGINEERS, MERSEYSIDE SECTION (at the Liverpool Engineering Society, 9 The Temple, 24 Dale Street, Liverpool), at 6.45 p.m.—Mr. J. B. Birks: "The Physical Applications of Micro-Waves".

Thursday, April 1

MINERALOGICAL SOCIETY (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Scientific Papers.

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. R. J. Halsey and Dr. J. H. Swaffield: "Analysis-Synthesis Telephony with Special Reference to the Vocoder".

INSTITUTION OF CIVIL ENGINEERS, NORTH-WESTERN ASSOCIATION (at the Engineers' Club, Albert Square, Manchester), at 6.30 p.m.—Mr. F. D. C. Henry: "The Development of Motorway Projects".

ROYAL STATISTICAL SOCIETY, SHEFFIELD GROUP OF THE INDUSTRIAL APPLICATIONS SECTION (in Room B1, Department of Mechanical Engineering, The University, St. George's Square, Sheffield), at 6.30 p.m.—Mr. G. Komlosy: "The Application of Statistical Quality Control to a Steel Strip Mill".

Thursday, April 1—Saturday, April 3

SCIENCE MASTERS' ASSOCIATION, SCOTTISH BRANCH (at the University, Glasgow).—First Annual General Meeting.

Friday, April 2

Society of Public Analysts and other Analytical Chemists, Physical Methods Group (at Birmingham), at 2.30 p.m.—Visit to the Physics Department of the University, Bristol Road, Edgbaston; at 6.30 p.m. (in the English Theatre, Mason's College).—Papers on "The Determination of Radioactive and Stable Tracer Isotopes".

Physical Society, Optical Group (in the Physics Department, Imperial College of Science, Imperial Institute Road, London, S.W.7) at 3.30 p.m.—Mr. C. G. Wynne: "Wide-aperture Mirror Lens Systems"; Mr. R. W. G. Hunt: Demonstrations.

Institution of Electrical Engineers, Measurements Section (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Discussion on "High-Speed Recording of Optical and Electrical Transients" (to be opened by Mr. H. A. Prime).

Royal Statistical Society, London Group of the Industrial Applications Section (at the E.L.M.A. Lighting Service Bureau, 2 Savoy Hill, London, W.C.2), at 6 p.m.—Dr. H. O. Hartley: "Some Short Cuts in Statistical Calculations".

Society of Dyers and Colourists, Manchester Section (at the Engineers' Club, Albert Square, Manchester), at 6 p.m.—Annual General Meeting.

Friday, April 2—Saturday, April 3

Association of Special Libraries and Information Bureaux, Northern Branch (at Leeds).—Conference.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer in Bacteriology at the Essex Institute of Agriculture, Writtle, Chelmsford—The Chief Education Officer, County Offices, Chelmsford (April 3).

Lecturer in Mathematics—The Principal, County Mining and Technical School, Nuneaton (April 3).

Head of the Chemistry Department, and Head of the Mechanical Engineering Department, in the Technical Education Branch of the Department of Public Instruction, New South Wales—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2 (April 5).

Teacher of Botany and Bacteriology in the Chemistry Department—The Principal, College of Technology, Belfast (April 5).

District Metallurgist, Mines Department, Southern Rhodesia—The Secretary, Office of the High Commissioner for Southern Rhodesia, 429 Strand, London, W.C.2 (April 7).

Chief Laboratory Technician for Pathology and Bacteriology Department—The Secretary, Rowett Research Institute, Bucksburn, Aberdeenshire (April 10).

Scientific Assistant in the Department of the Chief Development and Research Officer—The Staff Officer (Ref. ER/E.467), London Transport, 55 Broadway, London, S.W.1 (April 10).

Secretary to the Institute—The Registrar, University College Institute of Education, Hull (April 10).

Senior Industrial Chemist and a Junior Industrial Chemist at the Atomic Energy Research Establishment, Harwell (for control of water supply to the Establishment, effluent disposal arrangements and general chemical service to the Chief Engineer, including control of boiler house, fuel economy, water treatment and large water distillation plants)—The Ministry of Labour and National Service, Technical and Scientific Register, Room 669, York House, Kingsway, London, W.C.2, quoting F.215/48A (April 12).

Research and Test Baker to the British Baking Industries' Research Association—The Ministry of Labour and National Service, Technical and Scientific Register, Room 669, York House, Kingsway, London, W.C.2, quoting F.179/48 (April 12).

Lecturer (Grade II) in Botany (Morphological)—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (April 15).

Lecturer in Chemistry in the United College, St. Andrews—The Secretary, The University, St. Andrews (April 15).

Senior Lecturer in Physics and a Lecturer in Physics—The Principal, Chelsea Polytechnic, London, S.W.3 (April 15).

Lecturer (Grade III) in the Department of Geography—The Clerk, Birkbeck College, London, E.C.4 (April 17).

Lecturer in Theoretical Physics and an Assistant Lecturer in Theoretical Physics—The Registrar, The University, Manchester 13 (April 17).

Superintendent of the Physics Division of the National Physical Laboratory in the Department of Scientific and Industrial Research—The Secretary, Civil Service Commission, Scientific Branch, 27 Grosvenor Square, London, W.1, quoting No. 2140 (April 21).

Principal Scientific Officer in the Armament Research Department of the Ministry of Supply—The Secretary, Civil Service Commission, Scientific Branch, 27 Grosvenor Square, London, W.1, quoting No. 2139 (April 22).

Senior Principal Scientific Officer in the Infestation Control Division of the Ministry of Agriculture and Fisheries—The Secretary, Civil Service Commission, Scientific Branch, 27 Grosvenor Square, London, W.1, quoting No. 2138 (April 23).

Entomologist in the Inter-territorial Tsetse Reclamation Department, East Africa—The Under-Secretary of State, Colonial Office (Research Department), Palace Chambers, Bridge Street, London, S.W.1 (April 24).

Lecturer (Grade II) in the Department of Psychology—The Registrar, The University, Liverpool (April 24).

Lecturer in Social Anthropology and a Lecturer in Public Administration, for the Department of Social Studies—The Registrar, University, Leeds 2 (April 24).

Professor of Mathematics—The Secretary and Registrar, University College of North Wales, Bangor (April 24).

Government Chemist in the Public Works Department of the Gold Coast—The Director of Recruitment (Colonial Service), 15 Victoria Street, London, S.W.1 (April 30).

Research Fellows in Physics and Chemistry, including physical and organic chemistry, biochemistry, chemotherapy, pharmacology and engineering (Fellowships for Scientific Research established by I.C.I., Ltd.)—The Secretary, The University, Edinburgh (April 30).

Lecturer in Mathematics, to teach Pure and Applied Mathematics, more particularly the latter—The Very Reverend the Dean, Christ Church, Oxford (May 1).

Lecturer in Social Anthropology, and a Research Assistant in Social Anthropology—The Secretary, University College, Gower Street, London, W.C.1 (May 1).

Lecturer in Vertebrate Zoology and a Demonstrator, for the Department of Zoology and Applied Entomology—The Secretary, Imperial College of Science and Technology, South Kensington, London, S.W.7 (May 15).

Lecturer (Grade II) in Marine Zoology (Fisheries) at Port Erin Station—The Registrar, The University, Liverpool (June 9).

Administrative Officer to the Pneumokoniosis Research Unit of the Medical Research Council at Cardiff—The Director, Pneumokoniosis Research Unit, Llandough Hospital, Cardiff.

Agricultural Chemist in the Department of Agriculture, British Guiana, to undertake analytical and advisory work relating to soil crops and animal nutrition—The Director of Recruitment (Colonial Service), Colonial Office, 15 Victoria Street, London, S.W.1.

Assistant Experimental Officer (male or female) in the Plant and Animal Products Department of the Imperial Institute, in the Intelligence Section—The Establishment Officer, Imperial Institute, London, S.W.7.

Lecturer in Physics—The Registrar, University College, Exeter.

Micro-Analyst in the Department of Organic Chemistry—Prof. W. Baker, The University, Bristol 8.

Senior Geologist for the Mines Department, Adelaide, to take charge and supervise geological investigations of the coal resources of the State and to advise on geological aspects of exploitation—The Agent-General for South Australia, South Australia House, Marble Arch, London, W.1.

Timber Marketing Officer by the Government of Nigeria Commerce and Industries Department—Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M/N/17860/3E.

MACHINERY OF GOVERNMENT

SEVERAL distinct trends in public affairs have directed fresh attention in recent months to the adequacy or otherwise of the existing instruments of government in meeting the post-war needs of Britain. The reorganisation of the defence ministries under a co-ordinating Minister of Defence and the tendency to enlarge the responsibilities of the Lord President of the Council for the oversight and co-ordination of scientific effort, making him in effect the Minister for Research and Intelligence suggested by the Haldane Committee of many years ago, have raised the question of the efficiency at the highest level of administrative organisation. The formation of the Defence Research Policy Committee and the Advisory Council on Scientific Policy, with their various sub-committees, is only one special aspect of the problem of relating knowledge to power at the very seat of authority. Sir Stafford Cripps' appointment as Minister for Economic Affairs was another indication of re-organisation in accordance with the recommendations of the Haldane Committee. The Government's programme of nationalization and the creation of the National Coal Board and similar national boards have also brought into question both the capacity of the Civil Service itself and the existing structure of government to deal competently and efficiently with the issues involved, while proposals for the re-organisation of local government and regionalism have likewise stimulated thought on these matters.

It will be recalled that in its fifth report of the 1946–47 session, the Select Committee on Estimates concluded that insufficient thought had been given to adapting the machinery of government to its new tasks, and referred to the danger that in spite of the formation of new ministries and the placing of much of the responsibility for the conduct of nationalized industries and like activities in the hands of quasi-governmental boards, certain Departments of State might have become too large and cumbrous to work as rapidly and efficiently as single administrative units. A reconsideration of the whole pattern of government in the light of modern conditions might well suggest a re-organisation that would increase the rapidity and efficiency with which the ever-growing volume of work is discharged. Even if this survey led to no reduction in staff, it should at least obviate further increases.

It has been objected that such a committee as that suggested by the Select Committee, consisting of a few highly placed and experienced persons from outside the Civil Service, would be less likely to yield practical results than a committee of permanent heads of Departments. Whatever substance there may be in that criticism, there can be no doubt that there are the gravest objections, as has been again pointed out by Dr. W. A. Robson in his able article on the machinery of government in the recent issue of the *Political Quarterly*, to the secret proceedings of the Cabinet committee on the machinery of government. The whole question demands public discussion, and it is well to note that besides Dr. Robson's article, this specific question is discussed by Mr. D. N. Chester in an article "The Efficiency of the Central Government" in the *Journal of Public Administration*, and is the subject of a discerning chapter in Mr. H. R. G. Greaves' recent book, "The Civil Service in the Changing State"*.

Dr. W. A. Robson reviews with approval the arrangements for co-ordinating the Service Ministries and defence policy under the Minister of Defence; but he points out that a ministerial hierarchy is already emerging, and that the effect of the concentration of power in the hands of five or six ministers calls for reflexion. He sees, it is true, in the creation of a Minister of Defence and a Minister for Economic Affairs a trend towards the recommendations of the Haldane Committee; but the growth of functionalism has already made the Home Office anomalous, while the Colonial Office and the Scottish Office are in part, at least, territorial concepts. Dr. W. A. Robson lends his own authority to the suggestion that the whole question demands impartial and objective examination by a committee possessing exceptional ability, great experience of public affairs, disinterestedness and freedom from ministerial preoccupations.

Dr. Chester's article is less concerned with the fundamental structure of the machinery of government than with its operation and the factors responsible for overloading it, and for the decline in the capacity of departments which it is believed has occurred in the last two or three years. None the less, the factors to which he directs attention only strengthen the argument for the early and authoritative review urged by Dr. Robson. It is true that little can be done immediately to counteract the detrimental effects of the demand of the war years on the health of most senior officers; but one certain result of the review of the structure of government at the highest level would be to relieve the tremendous strain which the present plethora of international and like conferences places on senior officials.

Time alone can rectify the defects due to the abnormal turnover among permanent secretaries in the Civil Service which has marked the last few years; but something could be done to redress the weaknesses resulting from the return to civil life of many of the more distinguished temporary members of the Service. On the other hand, there are certain factors which at present favour the central administration, and Mr. Chester does well to point out that they are temporary. The diminishing respect for law which is so marked a characteristic of the post-war years cannot be expected to leave the process and execution of administration untouched. The British people have been accustomed to administer themselves, and a central administration which forgets that fact and does not seek to enlist the support and understanding of the governed is inviting trouble through the breeding of lawlessness.

Mr. Chester, like the Select Committee on Estimates, points clearly enough in general terms to some of the needs and dangers of the present situation. Overloading the administration almost inevitably means that there is no shedding of work which is not essential so as to concentrate on the big national issues. It means, too, that no attention is given to the use of devices to facilitate the execution of policy without employing large numbers of officials, and it is equally unlikely that effective use will be made of outside ability and experience.

These are all urgent needs if the Civil Service is to cope efficiently with the tasks that are now being laid upon it; but they are unlikely to be met unless at the highest level the structure is such that excessive strain is removed and those concerned with the formulation of policy are alive to what is administratively possible rather than politically desirable from the party point of view. The first task must indeed be to take the examination of this whole question right out of the arena of party politics and examine it scientifically and objectively, as it was examined by President Roosevelt's Committee on Administrative Management.

Mr. Greaves' analysis of Treasury control in relation to the machinery of government is no mean contribution to the understanding of the whole subject. In particular, a very fair appreciation of the way in which the Treasury has already adapted itself to the better co-ordination of policy relating to Civil Service matters indicates a series of further administrative needs, arising in part out of the Treasury's financial responsibility and in part out of its general co-ordinating function as the department of the Prime Minister. There are doubts as to whether the Treasury is sufficiently intimate enough with the work of other Departments to fulfil such co-ordinating functions, particularly the periodic review of departmental organisation. There are also doubts whether the Treasury has equipped itself for dealing with the new and different problems in the field of social services, and of the economic and industrial undertakings for which the State has developed varying degrees of responsibility.

Mr. Greaves brings out very clearly that provision is required for co-ordination at two levels. The first is at the ministerial level, where the task normally belongs to the Cabinet and where further delegation of more onerous parts of its work may be necessary on lines indicated by the appointment of a Minister of Defence. The second level is that of secretariat, and here Mr. Greaves stresses the necessity for something in the nature of a super-departmental staff to advise the Prime Minister in particular and the Cabinet as a whole.

An authoritative body to create and maintain the machinery of government—a directive authority for the scientific ordering of public administration in the larger and more complex connotation of that term in the modern social-service State—is considered by Mr. Greaves to be of high importance. He appears to visualize this as a permanent feature of the structure of government. Another need is for an agency of information and public relations, the function of which would be to organise and foster at every level of execution plans for the understanding and co-operation of the public—a need which has been consistently ignored by the present Government and repeatedly stressed by constructive critics, notably in certain P.E.P. broadsheets.

---

* The Civil Service in the Changing State. By H. R. G. Greaves. Pp. 240. (London: George G. Harrap and Co., Ltd., 1947.) 10s. 6d. net.

The need for an informed public opinion is increasingly apparent, but it is not so widely appreciated that an informed public implies a conscious effort to inform it—a blend of the arts of publicity and education. Mr. Greaves does not make the mistake of imagining that attention to administrative needs, the provision of means for the periodic overhaul and review of the general lay-out of departments and the distribution of responsibility at the top will suffice. The scientific treatment of establishment matters, including recruitment, promotion, physical conditions of work over the whole field of public service, and research in the whole field of government are also necessary. Information must flow adequately upward as well as downward, and a new temper must be infused into the whole field so as to secure, at the highest level, clear thinking on administrative organisation, firm direction, fundamental reforms and strenuous and sustained endeavour. The segregation of the central official must be overcome, and the whole service brought into closer contact with the spirit and tendencies of the new society. Only when clear understanding of the issues is developed on both sides can we expect either the imaginative and bold reforms and experiments in administration to be initiated, or the public support and co-operation which are indispensable for the enactment of policies thus conceived.

That the danger of bureaucracy does exist as the public service becomes more efficient is made plain by Mr. Greaves; many others have done the same since the Haldane Committee directed attention to the point in emphasizing the necessity of real Parliamentary control being enforced so as to keep pace with any improvement in departmental methods. What must be stressed above all is that we have here a searching test of democracy, which makes high demands on the Government at all levels and also on the private citizen. Whether democracy can meet that test has yet to be seen, but the issues are at least made plain. The Haldane Committee was fully aware in making its suggestions that an efficient departmental system working in satisfactory relation with Parliament could not be established or maintained on lines laid down in advance by any committee of inquiry. The practical efficacy of the principles which the Haldane Committee suggested depends upon the zeal and discretion with which they are applied from day to day by Parliament, by Ministers and by the officers of Departments.

These are the living forces whose spirit is essential to any form of government that is more than a machine; and while we may yet have to evolve, as a result of further experiment, the forms of organisation and the rearrangement of duties which will best serve the needs of the social-service State and preserve the values of democracy, there can be no question that the forces have sometimes been ignored by the Government to an extent dangerous to the existence of a free society. Parliament as ultimate authority must, as Sir John Anderson said in his Romanes Lecture, have adequate opportunity for inquiry, for debate, and for passing judgment. To curtail that opportunity, in order to serve the dictates of a party legislative programme, is as fatal to democracy as the totalitarian treatment of human beings as though they were inanimate objects. There may be no science of statesmanship or politics or persuasion, as Prof. A. D. Ritchie holds. But the study of government and administration holds both promise and profit; and not the least for the growing emphasis on, and understanding of, the human factor both among those who govern and who are governed, which marks these attempts to analyse the problem to-day and to present some approach to a solution.

TREES IN PROSE AND PICTURE

Handbook of the Trees of the Northern States and Canada, East of the Rocky Mountains

By Romeyn Beck Hough. Pp. x+470. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1947.) 28*s*. net.

Trees for Town and Country

A Selection of Sixty Trees suitable for General Cultivation in England. Prepared for the Association for Planning and Regional Construction by Brenda Colvin and Jaqueline Tyrwhitt; with drawings by S. R. Badmin. Pp. 132. (London: Percy Lund, Humphries and Co., Ltd., 1947.) 25*s*. net.

INTEREST in trees has increased with the augmented interest in gardening, while the recognition of the merits of roadside planting and the amenity value of trees in the modern vast conurbations has developed the need for more information concerning the exotic species. Moreover, the shortage of timber supplies has involved the economic exploitation of a wider range of species for many purposes and thus stimulated interest in them from other aspects.

Mr. Hough's handbook of the trees of the northern United States and Canada is chiefly notable for the excellent illustrations and the thought devoted to their preparation. This work deals with twenty-three species of coniferous trees and one hundred and eighty-five broad-leaved species. Each of these is illustrated by means of photographic reproductions of the foliage and fruits, the winter condition of the twigs and the appearance of the trunks. For most of the species distribution maps are also provided, and in many instances a photomicrograph of a transverse section of the timber. The use of a background grid for the details and of a rule in all the photographs of trunks enables the reader to assess the scale of reduction. In view of the excellence of the illustrations it seems almost ungracious to cavil at the omission of photographs of the flowers, and the difficulty of recognizing the limits of the foot-rule in front of not a few of the tree trunks.

The book should have a wide appeal, and not least in Great Britain, where American trees have been so long cultivated and prized. To the student the descriptive matter contains much of value and interest; and a perusal of the distribution maps will recall many noteworthy features, as, for example, the large proportion—some 72 per cent—of arboreal species more or less restricted to the eastern half of North America, and the small proportion which are restricted to the western half, while a few afford examples of discontinuity, particularly the swamp species *Leitneria floridana* found as a native tree in Florida and again from Missouri to Texas. The few species confined to the western States comprise two conifers and two poplars.

Keys are provided to the genera and species, although as these depend in large part on reproductive characters their usefulness is limited. The text and illustrations of this work together constitute a valuable and convenient source of information that will be of service alike to the botanist, the arboriculturist and the forester.

"Trees for Town and Country" is a book of a more utilitarian character in which the emphasis is naturally placed upon growth and habit rather than on details of morphology. Each of the sixty species selected is illustrated by a full-page photograph. Many of these are excellent both as typifying the species portrayed and as tree portraits; but a few scarcely do justice to their subjects, as, for example, those of *Catalpa speciosa, Prunus avium* and *Carpinus betulus*, and, particularly with respect to the last-named, fail to convey their potentialities. The hornbeam is a really superb tree when allowed to develop properly, although this is too little realized because its tolerance of trimming and pollarding has so often destroyed its intrinsic merits both in winter and summer.

Each photograph is accompanied by line drawings by S. R. Badmin which are both useful and charming, representing, as they do, the details of structure, the winter appearance and the average heights of the species at various ages, so that the prospective planter can judge the space required and the probable effect on the landscape. The figures are accompanied by short notes on soil, climate, growth and cultural details.

For the tyre especially, this work should prove a very real aid in assessing the merits of the more familiar subjects; though it must be borne in mind that such selections as this suffer from the defects of their merits and may, unless used with caution, lead to stereotyped planting and failure to utilize species such as, for example, *Prunus padus, Tilia parvifolia, Tilia petiolaris,* and *Sorbus torminalis,* which though not included here, may, in certain circumstances, have a prior claim to consideration.

E. J. SALISBURY

BRAIN AND MIND

The Physical Background of Perception

By E. D. Adrian. (Being the Waynflete Lectures delivered in the College of St. Mary Magdalen, Oxford, in Hilary Term 1946.) Pp. viii+95. (Oxford: Clarendon Press; London: Oxford University Press, 1947.) 10*s.* net.

PHYSIOLOGY has been defined as the outcome of a curiosity about ourselves. Such curiosity reaches its peak in the attempt to discover what material events in the brain accompany, and might be responsible for, the conscious processes of feeling and thought. The brain–mind relation is the no-man's-land on which the theologian, the psychologist and the physiologist meet face to face. The problem is age-old, and no immediate solution is in sight. The physiological approach has, however, advanced somewhat in recent years. This has been chiefly due to the work of Prof. E. D. Adrian at Cambridge, who summarized the present position in his Waynflete Lectures at Magdalen College, Oxford, in 1946, which are now available.

Prof. Adrian starts from the point that what goes on in the brain is to a large extent determined by what comes into it from the sense organs. It is firmly established that only one type of nervous message, the standard nerve impulse, is transmitted in the nervous system. There is thus only one common form of signalling available, and the message signalled depends for its qualitative interpretation on where it has come from and where it arrives. The sense organs sensitive to one particular type of physical or chemical change are connected by their own private pathway to one particular part of the cerebral cortex, which constitutes the cortical area in which that particular sensation is perceived. Within each cortical area there is a spatial localization of the different parts of the peripheral sensory field. The cortex may thus be regarded as a sensitive screen on which is projected a map or replica of the external world as appreciated by the sense organs.

This cortical projection of sensory data is a concrete reality; it is a pattern of electrical activity which can be mapped out in considerable detail by physiological methods. The map has been fully studied in anæsthetized animals, and the main conclusions have been confirmed in man during surgical operations on the brain. There is no direct proof that the intensity and duration of a sensation are strictly related to the temporal pattern of nerve impulses arriving at the cortex, but the accumulation of much indirect evidence makes this highly probable. One important point, which Adrian's work has clearly brought out, is that the size of the cortical area allocated to a particular sensation coming from a particular part of the body is not determined by the size of the sensory field concerned but rather by the importance which that particular part of sensation has for the conscious behaviour response of the animal. Naturally this varies considerably in different species. In the pig, for example, the tactile area for the snout is quite disproportionately large as compared with that for the rest of the body and with other species. In man, the tactile area for the hand is much bigger than that for the foot.

The arrival of sensory impulses in the cortex can be studied in the anæsthetized animal; but the next stage, the inquiry into what happens in the brain after the impulses arrive, and the relation of this to mental processes, must be pursued in conscious man. Here the technical difficulty that electrical recording can, ordinarily, only be carried out through the thickness of the skull precludes any very exact localization. Nevertheless, one very important and unexpected discovery has been made. When the cortex is inactive, as during anæsthesia, in sleep or simply during inattention, there is a synchronous rhythmical activity of the cortical cells at a frequency of 7–10 impulses per second (α-rhythm). This rhythm originates in the parieto-occipital area, but extends over the greater part of the cortex. When conscious attention is given to what is seen, or when mental calculations are performed, the rhythm disappears or is replaced by a faster local rhythm. The transference of conscious attention to one particular area of the cortex appears to involve the setting free of that area from the basic α-rhythm so that it can be used by the 'mind'. The only prerequisite for the existence of consciousness seems to be that some part of the cortex, and not necessarily a large part, should be freed from the α-rhythm and so made receptive to incoming sensory messages. The mechanism which suppresses the natural α-rhythm and so causes, or allows, consciousness, does not reside in the cortex itself; it appears to originate in the upper part of the brain stem and almost certainly involves the hypothalamus.

So far a mechanistic interpretation suffices; but when we inquire how the brain recognizes and remembers things, very serious difficulties arise. For example, we know that a tune is recognized whatever its key, and a shape is recognized whatever its size and whatever part of the retina its image falls on. So it is obviously not a precise stimulation of certain nerve cells which the cortex recognizes; it must be some abstract pattern or concept which the brain in some way distils from actual sensory data and stores in its memory. Similarly, on the motor side, once a complex skilled movement has been learnt, it can be carried out, though less perfectly, with quite different muscles. Recognition and habit formation cannot, therefore, be due to the facilitation of particular nerve pathways by repeated use. On the sensory side, there must be something which abstracts the significant elements of a pattern; and on the motor side, something which converts an abstract idea of movement into an actual movement.

It is just here that all mechanistic hypotheses seem to break down, and it is in this that the brain differs from all man-made contrivances such as gun predictors, mine detonators and calculating machines. These machines respond when a certain fixed pattern of stimulation reaches a certain threshold. The brain, on the other hand, responds to an abstract pattern and is not tied to a critical threshold of stimulation. Indeed, the property of adaptation, so characteristic of the nervous system, renders it singularly inefficient in the recognition of absolute intensities of stimulation; it can only be relied upon to compare one thing with another.

This is the fundamental problem which confronts those who seek to explain mental processes in physiological terms. Adrian himself can see no immediate prospect of its solution, but he directs attention to certain ideas of Lashley and of Craik which might afford an approach. He concludes that, as contemporary physiology is unable to give a satisfactory account of any kind of mental activity, there is, as yet, no risk of its incursion into the field of metaphysics.

O. A. Trowell

MEDICAL DISEASES IN HOT CLIMATES

Memoranda on Medical Diseases in Tropical and Sub-Tropical Areas. (War Office)

Eighth edition. Pp. 396 (37 plates). (London: H.M. Stationery Office, 1946.) 7*s*. 6*d*. net.

As vast numbers of troops were engaged in campaigns in the Pacific, South-East Asia and the Middle East, it is not surprising that many advances in medical knowledge of tropical diseases were made during the last four vital years of the Second World War. Much of this new knowledge is included in the present publication.

The book comprises thirty-nine memoranda arranged in alphabetical order. New articles are included on nutritional diseases, infective hepatitis, tropical eosinophilia, leprosy and the sulphonamides.

The section on arthropod pests contains pertinent information on the various uses of *D.D.T.* in the control of both the wingless and winged pests. Its special value in the destruction of mosquito larvæ and adult anophelines, house flies and lice is emphasized. *D.D.T.*, however, was ineffective in preventing scrub typhus, and here dibutyl-phthalate applied to clothing proved the repellent of choice, as it afforded most effective protection against the larval mite vector.

An instructive account is given of infective hepatitis based on the 'Alamein Line' outbreak affecting 10,000 troops. This is followed by a consideration of arsenical and homologous serum jaundice—both of which resemble in many respects infective hepatitis. The view is accepted that both these conditions are caused by inoculation with blood or serum containing a virus or some allied icterogenic agent. The comprehensive account on cysticercosis is abridged from the classical work of MacArthur on this subject; it is now gratifying to read that the more recent follow-up of Dixon and Hargreaves shows the prognosis to be brighter than was at first supposed.

The view that secondary invading organisms play an important part in those chronic cases of amœbiasis which prove intractable to amœbicidal drugs is accepted; preliminary treatment with sulphonamides and penicillin is advocated in such circumstances.

As a result of field experience with bacillary dysentery, it is advised that all individuals developing diarrhœa should be immediately treated with sulphaguanidine. This procedure not only reduced hospitalization by preventing the development of clinical dysentery, but also eliminated carriers and cut short epidemics through destruction of dysentery bacilli in the stools.

In the chapter on malaria, some twenty-four out of thirty-six pages are devoted to treatment. Doubt is expressed whether intramuscular 'Mepacrine' can replace intravenous quinine in the urgent treatment of cerebral and algid malaria. The great value of 'Mepacrine' as a suppressive in a dosage of 0·1 gm. daily is emphasized, resulting, as it does, in the radical cure of malignant tertian malaria and the suppression of benign tertian infections. The statement is made that "its use in the 1939–1945 war gave us great tactical advantages against the Japanese—we could operate in malarious areas which they had to avoid". While the first part of this statement is undoubtedly correct, it is doubtful if the Japanese ever considered the military implications of malaria or of any other disease in their forward planning.

A valuable addition to future editions would be the inclusion of graphs based on statistical data showing the dramatic reduction in the incidence of diseases like malaria, bacillary dysentery and scrub typhus following the introduction of preventive measures and chemotherapeutic control during the later phases of the Pacific and Burma campaigns.

As stated in the preface, the aim of this book is to give medical officers something that can be more easily carried about than a text-book and yet offer in a concise form the essentials of the more important diseases of the tropics. This objective has been splendidly achieved in the eighth edition.

N. Hamilton Fairley

THE THERMIONIC CATHODE

Les cathodes chaudes

Théorie et pratique. Par Charles Biguenet. Pp. 183. (Paris: Éditions de la *Revue d'Optique théorique et instrumentale*, 1947.)

AMONG many recent books under the general heading of electronics, there has been until now no comprehensive account of the basis of the subject; the thermionic cathode. While it would not be true to say that the well-known books by Reimann, T. J. Jones or de Boer are out of date, there have been developments in the past ten years with which both the student and the technician should be familiar; none of these books was intended to appeal to the valve designer or to deal with the technique of preparing thermionic cathodes and persuading them to liberate electrons according to the mathematical formulæ. For these reasons any modern account of the theory and practice of such cathodes is to be welcomed.

In the present book there is a detailed account of those properties of tungsten relevant to its use as a thermionic cathode, which will be of considerable value to the technical reader, while the section on thoriated tungsten is almost as comprehensive. There is a discussion of the process of carburizing, which is welcome as there is little literature on this subject, while the theory of the thoriated filament is adequately covered. The section on oxide cathodes is well written, with a modern approach, and summarizes the earlier information in the light of the present ideas of the behaviour of semi-conductors. The practice of the preparation and application of coatings is described, and also their treatment; while the author presents his own theory of oxide coatings and the difference between pulsed and continuous operation. This may justify discussion elsewhere. The remainder of the book gives a short account of other types of cathode, and of associated techniques such as high-vacuum technique, eddy-current heating and the application of the electron microscope.

One statement which is surprising is (p. 70) that hydrogen raises the work function and lowers the emission from tungsten. The original observation to this effect by Langmuir was found erroneous, as discussed, for example, by Reimann ("Thermionic Emission", p. 178). There are statements where it would be helpful if an authority were quoted or if the evidence were indicated; for example (p. 100), "if the degree of carburising of a thoriated filament is less than 6%, the filament remains sensitive to traces of gas", and (p. 129) "the normal operating temperature of an oxide cathode is from 850° to 900° C.". An important omission occurs in discussing the relation between temperature and current in a thoriated filament, where no reference is made to the importance of the geometry of the filament.

These are points of detail. A general comment is that the value of the book would have been increased if further practical information had been included, possibly at the expense of the adaptations from de Boer's book on adsorption. For example, there is little actual information about the pulsed operation of oxide cathodes, and none about the pulsed operation of thoriated filaments, or of their use with high-anode voltages. There is no discussion of gettering techniques and their relation to emission development and maintenance. There is, in fact, no indication that, in practice, difficulties are frequently encountered with cathodes of all types in obtaining or maintaining the theoretical performance. Thus we are not told whether thoriated filaments do in practice give the lives predicted by Langmuir's tables, while it may cause alarm and despondency among those concerned with valve manufacture and development to read that, after a prescribed treatment of an oxide cathode, "le tube est bon à couper et son émission électronique restera stable". The matter is not always so simple, especially with modern short-wave valves requiring high-current density.

D. A. WRIGHT

ICE CREAM

The Ice Cream Industry

By Grover Dean Turnbow, Prof. Paul Hubert Tracy and Lloyd Andrew Raffetto. Second edition. Pp. ix + 654. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1947.) 6 dollars.

IT is a commentary on the trend of life that a book of nearly 700 pages should be written on a comparatively small item of diet, an item which, until a few years ago, was either regarded as a luxury or as a special treat for small children. This one item has now become the basis of one of the big food industries, ice cream manufacture, and it must be admitted that ice cream is a useful and palatable method of inducing people to take more milk. Messrs. Turnbow, Tracy and Raffetto have in this revised edition brought their earlier work, of 1927, up to date; have added chapters and rewritten chapters, and the result is a very readable compendium of knowledge (there are a number of minor and several major errors particularly in the scientific parts) dealing with every aspect of ice cream, from manufacture to salesmanship. It would be an interesting study to try to decide which author has been responsible for the various sections, for they are not all of one style, and one gets the feeling of a vision of patchwork quilt.

From the point of view of the chemist, the scientific portions are interesting; but one might question the desirability of including in a book of this nature explanations of some of the underlying scientific principles of physical chemistry. It must be remembered, however, that in the United States there are courses at universities and at technical colleges dealing with the manufacture of ice cream, and the authors state that their review of the physico-chemical properties is for the advanced student. One cannot but feel that the elementary mathematics included in the section dealing with control and standardization is a strange bed-fellow for the physico-chemical theories.

In these days of austerity in Great Britain, it is refreshing to know that on the other side of the Atlantic such a wide range of delectable sweetmeats is still to be had—plain ice creams, fruit ice creams, nut ice creams, confection ice creams, bisque ice creams, ice puddings, parfaits, mousses, and so on, to mention but a selection. To-day, in Britain, there is a welcome interest in food-borne infections, and therefore the statements regarding this danger are of particular import. One could wish that the advice given in the chapter on "Washing and Sanitizing" (!) could be brought to the notice of all manufacturers and purveyors of ice cream in this country.

Having watched children and adults in Britain eating ice cream, the following (p. 385) from the chapter dealing with the food value appears to the reviewer to be of great importance: "Too rapid eating or drinking of large quantities of ice-cold foods may be one of the factors responsible for some of the gastro-intestinal disturbances occurring during the summer months. Any discomfort from consuming ice-cold foods can be avoided by eating slowly, thus allowing the digestive system to function normally."

The survey of refrigerating practice is a concise summary of present practice and well worth study.

Everyone concerned with the production of ice cream may be advised to read this book.

L. H. Lampitt

NORTH AMERICAN ARCHÆOLOGY

Indians before Columbus

Twenty Thousand Years of North American History Revealed by Archæology. By Paul S. Martin, George I. Quimby and Donald Collier. Pp. xxiii + 582. (Chicago: University of Chicago Press; London: Cambridge University Press, 1947.) 33*s.* net.

The authors of this book open their preface by saying that it has been written for the interested layman and for students taking introductory courses in anthropology, but that it is not intended as a general reference book for professional anthropologists. It can be said at once that it is a very useful work, though the greater part of it is likely to appeal more to the specialist, at any rate outside North America, than to the classes for whom it is intended.

The book is divided into eight parts, of which the first two are introductory, the third deals with the earliest American cultures, the next four describe the subsequent North American cultures under the headings of four great natural regions, and the eighth is a concluding summary with correlations. Part 1, entitled "Background", is frankly popular, but it includes a useful summary of how the New World was populated, and a brief, straightforward exposure of a number of hoary fallacies concerning the Indian. Part 2, on arts and industries, summarizes the methods of manufacture of various materials, and ends with a most useful account of what is known about trade and commerce in ancient North America. These chapters are admirably suited to the needs of the people for whom the book was designed; but more advanced students also will read them with pleasure, and very likely with profit, since they contain some new information. Few, for example, can have known that bannerstones and other unexplained objects of slate were really weights for spear-throwers. A valuable feature of Part 3 is the outline it gives of how early cultures, like the Cochise, led up to the better-known cultures of the south-west. There was no hiatus, only a very slow development, until the introduction of agriculture and pottery provided the stimulus to more rapid change.

The next four parts constitute the bulk of the book, and archæologists outside North America, who have had difficulty in following the numerous papers which have appeared within recent years and in forming a general picture from them, will find this the most useful section. The descriptions, competent though they are, will not of themselves be sufficient for this type of reader, but he will find what he needs to supplement them in the excellent lists of sources which accompany each chapter. On the other hand, elementary students and most interested laymen will require far more illustrations to lighten and give meaning to the closely condensed pages of facts. What illustrations there are might be rather more evenly distributed; many cultures have none, but, for example, the striking art of Key Marco in Florida has two whole pages. Each culture is described so far as possible according to a uniform plan, which facilitates reference, and in each case 'conjectures' are, by a wise provision, kept under a separate heading at the end.

The production of the book is excellent, the illustrations are good, and the main culture areas are clearly shown on a map occupying the end papers. The title deserves a word of criticism; North American archæology does not end with Columbus, and fortunately the contents of the book show that the authors do not really imagine that it does. Within the limits outlined above, it is a most valuable work.

G. H. S. Bushnell

ANIMAL PARADE

Parade of the Animal Kingdom

By Prof. Robert Hegner, assisted by Jane Z. Hegner. Pp. vii + 675. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1946.) 20*s.* net.

The fact that this is the ninth reprint of a book first published in 1935 is sufficient evidence that it meets a widespread demand for a general natural history which will give in one volume some information about the modes of life and activities of various common animals. The authors have chosen representatives from each of the main phyla, arranged in order of their complexity from *Amœba* to man; but the basis of selection is somewhat original and one finds not only animals familiar in everyday life, or economically important for food, fur, etc., but also unusual animals, such as those commonly seen in circuses and zoological gardens, animals familiar in literature, prehistoric animals, and even the unicorn, werewolf, and other mythological animals.

As might be expected the greater part of the book, about two-thirds, is devoted to vertebrates, and half of the remainder to insects; but the examples are well chosen and a surprising amount of information about the remaining groups is given in short space. It should be emphasized, however, that the book is intended primarily for American readers and the complete absence of any scientific names sometimes introduces a certain ambiguity. Thus, harvest-men (Phalangids) are referred to as daddy longlegs, a term which in Great Britain is usually applied only to crane flies (Tipulids). The fur of the weasel is stated to turn white in winter, while in Britain the term weasel is reserved for *Mustela nivalis* the coat colour of which does not change in this way. In North America the term weasel seems to be synonymous with stoat or ermine.

There are 743 illustrations, but their reproduction leaves much to be desired; a certain number, including some of the Cœlenterates and Vermes, are obviously photographs of museum models; and a few are photographs of stuffed museum specimens, the gibbon being a particularly unfortunate example.

These are minor drawbacks, however, and the work can be recommended as a useful general natural history. The success of the earlier editions has made it possible for the present one to be sold at the price of twenty shillings.

Edward Hindle

Synthetic Resin Chemistry

For Students. By Dr. S. R. W. Martin. Pp. vii+160. (London: Chapman and Hall, Ltd., 1947.) 15*s.* net.

DR. MARTIN'S book is best considered as an extremely practical guide to laboratory experiments for the student of synthetic resin chemistry, interspersed with an introductory survey of the theoretical side of this complicated field. The fifty-odd experiments are novel and well chosen; and it is difficult to know where else one could find details of such an illuminating series. They are simple, they are specific, and they work. On this score the book is wholly admirable.

Nevertheless, it is perhaps not unfair to doubt whether the accompanying theoretical matter, condensed and simplified though it is, will be smoothly absorbed by the type of reader visualized by the author in his preface—the student whose chemistry is of school certificate standard. This is no carping criticism; for the difficulty is one which must be faced squarely by anyone attempting to instruct the junior student in a technological subject with organic chemistry as its fundamental basis. True, the author devotes some twenty pages to a survey of elementary organic chemistry; but this alone is likely to prove heavy fare for the young chemist fresh from a school certificate course. It would appear essential to stipulate, not merely to hope for, "an elementary knowledge of organic chemistry" as a proper basis for the appreciation of the book. Taken, however, not on its own, but as an accompaniment (or, better, as a sequel) to a systematic elementary course in both aliphatic and aromatic chemistry, the book will be an invaluable guide to the embryo surface-coating technologist.

It may be hoped that in any subsequent edition the author will broaden slightly his title and terms of reference so as to include the cellulosic materials. As it stands, the book is useful only to the student in that section of the surface-coating industry dealing with phenoplastics, aminoplastics and alkyds: expanded slightly, its usefulness would extend to workers in all sections of the field.

P. D. RITCHIE

The Framework of Human Behaviour

By Dr. Julian Blackburn. (International Library of Sociology and Social Reconstruction.) Pp. viii+158. (London: Kegan Paul and Co., Ltd., 1947.) 12*s.* 6*d.* net.

THIS book, presenting in small compass an extraordinary mass of learning and research, the research of others being amply acknowledged, deals, as the title says, with the framework of human behaviour. That framework connotes the equipment with which any person is endowed before he begins his individual development in society. Part of this endowment is due to hereditary factors, and part to the kind of environment in which he has been born. In this book, by no means the author's first production on the subject, he considers the part played by heredity and environment in the physical and mental make-up of individuals, and the part played by sex and racial differences. He then goes on to discuss the behaviour of groups, national and social, and the influences by which they are motivated. The reader will need to know something of the modern psychologist's use of the word 'pattern'—definable as a complex whole, characterized by a definite arrangement or interrelation of parts; as a behaviour pattern or a pattern of brain activity, Many readers will find good use for the eighth chapter. entitled "Conclusion". The abounding references to other books are minutely careful. Dr. Blackburn has, in publishing this volume, made a substantial addition to the International Library of Sociology and Social Reconstruction.

What People Are

A Study of Normal Young Men. By Clark W. Heath, in collaboration with Lucien Brouha, Lewise W. Gregory, Carl C. Seltzer, Frederic L. Wells and William L. Woods. Pp. xvi+141+4 plates. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1946.) 11*s.* 6*d.* net.

THIS book should be welcome if only because it deals with an unusual subject. In both Britain and the United States much time, energy and financial support have been given to investigations of the mentally and physically ill and handicapped; but little attention has been paid to well people, upon whom depend the leadership and work of the world. Yet knowledge of the normal is of great concern in medicine, education, business and government. This report is based chiefly upon the study of selected Harvard undergraduates, but groups of men in the armed forces and in civilian life have been investigated as well. Selection of college students was made on the basis of all-round good adjustment, good health and academic success. The approach is clinical. Characteristics of normal young men are described from the points of view of medicine, physiology, anthropology, mental measurements, socio-economics and psychiatry.

The authors make no pretence that this is a completed work, or that they have the answers to many important problems which they have presented. The field is a large one and much remains to be done.

One word more. We in Britain are bound to ask what about the normal young women, who are by no means content to leave all the leadership to the men, whether in medicine, education, business, or government?

Making Your Own Telescope

By Allyn J. Thompson. Pp. xi+211. (Cambridge, Mass.: Sky Publishing Corporation, 1947.) 3.50 dollars.

TELESCOPE making by amateurs has a great vogue in the United States. In association with the Hayden Planetarium in New York, there has, for almost a dozen years, been an Optical Division of the Amateur Astronomers Association. Facilities and space have been provided in the basement of the Planetarium for classes in telescope making. Mr. Thompson has for some years been the instructor of these classes and has had ample opportunity to develop and test efficient and practicable methods and to become familiar with the various pitfalls and difficulties that beset the beginner. In order to make available to a greater number of amateurs the experience that he has gained, this book has been written. It describes in some detail the methods of grinding, polishing, figuring and testing mirrors, as well as methods of correcting the more common defects, with many useful hints. The other parts of the telescope are not neglected, and descriptions are given of simple pipe mountings, the construction of which does not require much mechanical ability.

A brief account of the history and development of the telescope is given in the first chapter.

The frontispiece of the book is a picture of the author's 6-in. $f/9$ telescope, with equatorial head and tripod mounting; made in accordance with the instructions in this book, it is stated to have cost less than thirty dollars. It may be recalled that William Herschel first embarked upon telescope construction because he could not afford to buy one for himself. With the aid of this book, many a budding astronomer should be able to construct his own telescope at a moderate cost.

Aircraft Strength of Materials

By Dr. H. D. Conway. Pp. viii+256. (London: Chapman and Hall, Ltd., 1947.) 21*s.* net.

DR. CONWAY has produced a book that should be valuable to both students and designers dealing with aircraft structures, but its title is misleading. It is entirely a work on the theory of structures, its secondary connexion with aircraft being that those problems that are of most interest in that field have been chosen, and the illustrative examples are such as occur in the peculiar types of structure occurring in aircraft construction. A critic could quarrel with the author for his sins of omission rather than commission, but incompleteness is inevitable in a book of this size. Also the science of the design of aircraft structures is so fluid at present that a selection of methods is bound to be one based on the author's personal experience. This defect is most noticeable in the part devoted to the behaviour of thin plates, which might have been much fuller. Its application to Wagner beams and stressed skin construction can scarcely be avoided to-day in the aircraft world; even the engine designer is meeting it now in the internal combustion turbine.

The layout of the book is excellent and logical. The chapters follow in an ordered sequence, and are well illustrated with numerical examples, particularly useful to a beginner. The more recent methods of structural analysis, such as the Hardy Cross method, are fully explained. This alone puts the book in a class by itself so far as an aeronautical reader is concerned.

The author has the courage to say that he has not tried to avoid the use of mathematics, claiming that no serious aircraft designer could be without such knowledge, a statement with which the reviewer heartily agrees.

Electronic Theory and Chemical Reactions

An Elementary Treatment. By R. W. Stott. Second edition, revised. Pp. viii+112. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1947.) 6*s.* net.

THE development of electronic theories of the mechanism of reactions has reached a stage at which it is possible to give useful general accounts of the main features, and there are indications of a rapidly growing interest in the subject. This interest has now deeply penetrated not only the ranks of teachers of chemistry who have a regard for major theoretical developments, but also the harder core of chemists in industrial and other fields who attach greater importance to tangible applications and concrete results.

The publication of a second edition of Mr. Stott's elementary treatment will be greeted with pleasure by those who were unable to obtain a copy of the first issue. This edition is almost identical with the first (see *Nature*, **153**, 510; 1944); at a time when the prices of many commodities are rising steeply and continuously it is a pleasure to note that the old price is retained. E. D. HUGHES

Mechanical Vibrations

By Prof. J. P. Den Hartog. Third edition. Pp. xi+478. (New York and London: McGraw-Hill Book Co., Inc., 1947.) 30*s.*

DEN HARTOG'S book combines mathematical simplicity with a rare insight into the physical nature of vibrations, and its author has a happy knack of explaining things in a way that the less gifted can understand. For these reasons, and for the wealth of information it contains, the book has long been a standard work in Great Britain as well as in the United States.

The present edition includes observations on helicopter rotors, the 'singing propeller' and oscillations of submarine periscopes. Electronic methods of vibration measurement and analysis, the damping of torsional oscillations in engine crank-shafts, oscillations excited by oil-film lubrication and 'flutter' are among important subjects which are discussed more fully in the light of recent work. This is a book of which no mechanical engineer should be unaware, and which those faced with vibration problems find of constant help. A. L. P.

Modern Assembly Processes

Their Development and Control. By J. L. Miller. Second edition revised. Pp. xii+199. (London: Chapman and Hall, Ltd., 1946.) 18*s.* net.

IN this new edition of his book, Mr. Miller has taken advantage of war-time experience to bring certain sections up to date; modern aircraft riveting practice in flush riveting and the invaluable pop riveting technique are described, for example. The descriptions of fluxes for soft soldering are considerably expanded and include recommendations for the lead/silver solders and the low-tin solders of B.S.219. Brief details are given of the newer welding processes such as Heliarc, the Elin-Hafergut process and automatic stud-welding machines. Apart from these additions, the book remains substantially the same as in the first edition and is still the only one available covering its specialized field. Mr. Miller has resisted all temptation to extend its scope, wisely preferring to restrict his words to the subjects on which his authority is undoubted. H. W. G. H.

Foundations of Chemical Theory

By Charles Simpson. Pp. viii+220. (London: University Tutorial Press, Ltd., 1947.) 6*s.* 6*d.*

THIS book aims at giving a concise account of the main principles of theoretical chemistry required for higher school certificate, intermediate science, pre-medical and first M.B. examinations, and providing a foundation for distinction and scholarship students. It actually contains rather less on many topics than is usually found in general text-books of this stage. More space is given to phase rule than is usual. A good feature of the book is the large number of questions and problems, which will provide useful exercises for students. Unfortunately, the book is marred by a number of minor errors, and in places insufficient detail is given to enable students to understand the principles of some experimental methods described. In a new edition the book should be carefully revised.

30-MeV. ELECTRON SYNCHROTRON

By D. W. FRY, J. W. GALLOP, F. K. GOWARD
AND
J. DAIN

Atomic Energy Research Establishment, Harwell

FOLLOWING earlier work on the conversion of a betatron to a synchrotron[1], a 30-MeV. electron synchrotron has been constructed and was first operated in October 1947. The machine is shown in Fig. 1, and employs a rectangular-yoke magnet, designed to give maximum space for experimental work. A more compact magnet, with eight C-shaped yokes, has also been designed by the English Electric Co., Ltd., for medical and industrial use, and is shown in Fig. 2; this magnet uses the same poles as that of Fig. 1, and should, therefore, give the same performance.

The machine has been operated so far only at 24 MeV. and at low gamma-ray intensity, because of temporary difficulties in protecting personnel. It is expected that the full output will be of the order of 10 röntgen/min. at 1 metre: the voltage will probably be a little less than the nominal 30 MeV. (see below).

Some of the techniques used in the construction of the machine are novel and will be emphasized in the brief description which follows. Details of the engineering practices used will, however, be omitted.

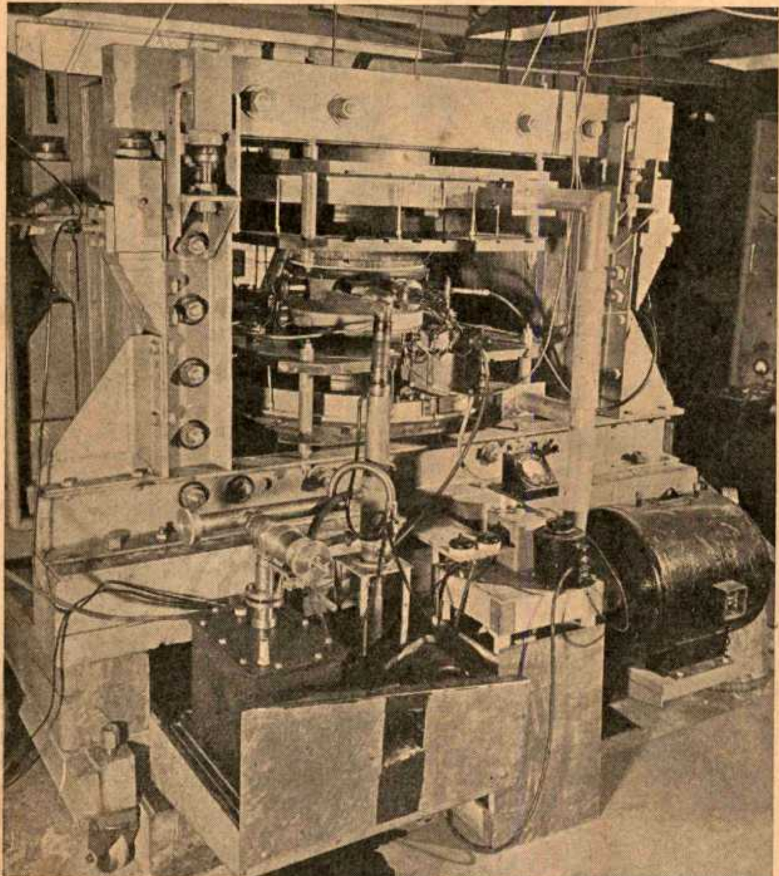

Fig. 1

The magnet of the synchrotron weighs about three tons and provides a peak field of 10,000 gauss in an annular gap of 10 cm. mean radius; the field in the annulus varies as (radius)$^{-0.7}$. The magnet is excited continuously, from the 50-cycle mains, by a resonant circuit carrying a reactive r.m.s. power of 1,500 kVa.; the losses in the circuit are about 25 kW. A betatron core is provided which accelerates the electrons to 2 MeV. (their velocity is then 0·98*c*), when the core becomes saturated. The laminations of the rectangular-yoke magnet are bent to follow the natural flow of flux, so far as is possible. This feature does not, however, achieve the desired result of reducing the normal field inhomogeneity of a betatron-type magnet. In particular the field disturbances due to eddy currents require correction, and this is achieved by inserting single-turn water-cooled coils between the pole shoes and the main pole cylinder. The coils are arranged to make the eddy-currents substantially equal at all points. The field homogeneity thus obtained, at injection, gives rise to a forced oscillation of the electron which occupies about one fifth of the space available for the electron orbits.

Difficulty has been experienced in starting-up the excitation circuit of the synchrotron, due to the change in the resonant frequency caused by the betatron core becoming saturated as the excitation increases[2]. This difficulty has been overcome by switching a portion of the condenser in and out. A variable choke has also been developed as an alternative method; this choke will be placed in parallel with the main coils of the magnet, and its inductance will be changed by a variable air-gap in its core. These methods allow for mains frequency changes as well as giving easy starting.

Two different types of 'donut' (evacuated annular chamber) have been developed and operated. For experimental purposes a 'donut' is formed from flat plates and cylinders waxed together[3]. For general use, blown 'donuts' in *F.C.N.* glass have been constructed by the Research Laboratories of the General Electric Co., Ltd.; one of these 'donuts' is shown in Fig. 3. The synchrotron just operates at a pressure of 5×10^{-5} mm., and the output does not improve as the pressure is reduced below 5×10^{-6} mm. With both types of 'donut' a pressure of 2×10^{-6} mm. is obtained consistently, with the electron gun and resonator operating; considerably lower pressures are obtained with the gun and resonator not operating. Sealed-off blown glass 'donuts' of similar design have also been used successfully.

The electrons are injected for 2 microsec., at a voltage of 10 kV. The electron gun is the standard type of Kerst betatron gun[3], which is placed on a variable mounting and is nominally at a radius of 11·5 cm.; the gun assembly is shown on the left-hand side of the 'donut' in Fig. 3.

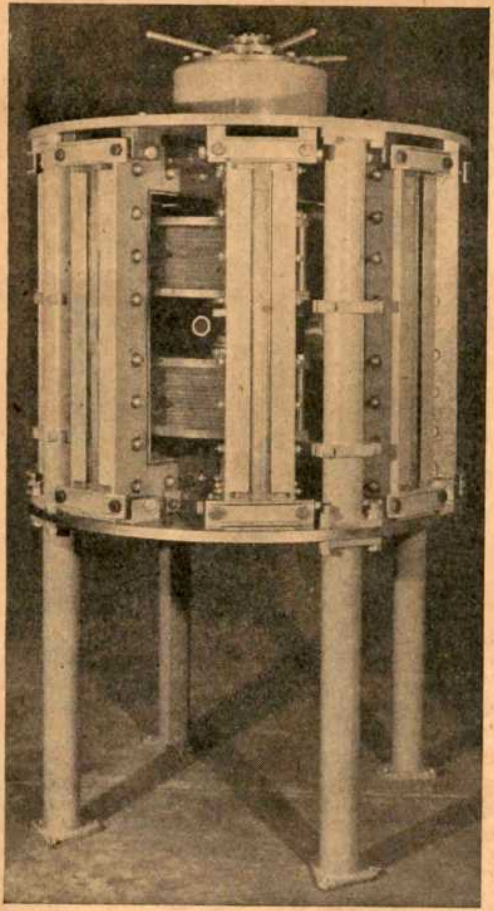

Fig. 2

The synchrotron acceleration is produced by a quarter-wave long radio-frequency resonator which is excited at 477 Mc./s. The resonator actually supplies about 10 V. per revolution to the electrons, but the voltage across its gap must be substantially greater than this, namely, about 100 V., to obtain stable synchronous operation and acceleration of a large fraction of the electrons. Some 8 watts peak power must be fed into the resonator losses to produce this voltage. In addition, power must be supplied to the electron beam to accelerate it. If the beam current in the synchrotron is assumed to be 1/100 microamp. at full output, the mean power required to accelerate this current to 30 MeV. is 0·3 watt, which means that the peak power required to be fed into the electron beam is about 2 watts. The total power required is, therefore, about 10 watts peak, and to give a safety margin 20 watts peak power is supplied to the resonator by a continuous wave oscillator and modulated amplifier. The relatively high efficiency of the resonator in this low-energy machine contrasts with the efficiency obtained in higher-energy machines, say 300 MeV., where the losses in the resonator are larger compared with the power used in accelerating the beam.

Two types of resonator have been developed, both made from high permittivity ceramic with a conducting silver coating fired on to it. The silver forms the inside and outside conductors of a coaxial line, and also forms the shorted back. A narrow accelerating gap in the inner conductor is burned by an arc. The resonators are made of Steatite and Porcelain Products Co.'s materials 'Tempradex', dielectric constant 15, and 'Faradex', dielectric constant 80. The resonators are so short that they need not be moulded to a circular shape as would be necessary with an air dielectric. The 'Faradex' resonator in particular is so small that no appreciable eddy currents are produced in it by the main field. It is therefore unnecessary to laminate it, and, further, it can be inserted into the 'donut' through a side-arm. The resonator is supported on a coaxial line which feeds it; it also has a second coaxial line attached, to monitor the voltage across the gap. The walls of the resonator are $\frac{1}{8}$ in. thick, and the internal conductor forms a rectangle 4·1 cm. wide × 2·8 cm. high; this dictates the area which is available for the electron orbits. Fig. 3 shows the resonator assembly, withdrawn from the 'donut' side arm.

The tungsten target is mounted internally and acts as a thin target. The electron orbits are allowed to shrink on to it, by switching off the radio-frequency accelerating voltage before the peak field is reached. This means that the acceleration ceases when the field at the equilibrium orbit is just over 9,000 gauss, which corresponds to an energy less than the nominal 30 MeV., namely, 28 MeV.

The switching operations required during each magnetic field cycle are the triggering of the electron gun modulator, the switching on and off of the radio-frequency, and the starting of the trace of the cathode ray tube display. This sequence was originally controlled electronically by pulses formed from multivibrators, which gave variable time delays relative to the pulse from a peaking transformer. This transformer was made from a strip of permalloy wound with a small coil and placed in the magnet gap. This system required frequent adjustment during operation, since the fields at which the switching occurred were dependent on the somewhat variable mains frequency. A system is now being used consisting of a series of peaking transformers, placed in series with the magnet excitation coils, and biased by D.C. windings to vary the field at which the pulses are produced.

A photograph of the main cathode ray tube display when the synchrotron is operating is reproduced in Fig. 4. The upper trace shows the rise of the magnetic field; its horizontal displacement is proportional to the field. The lower trace shows the falling magnetic

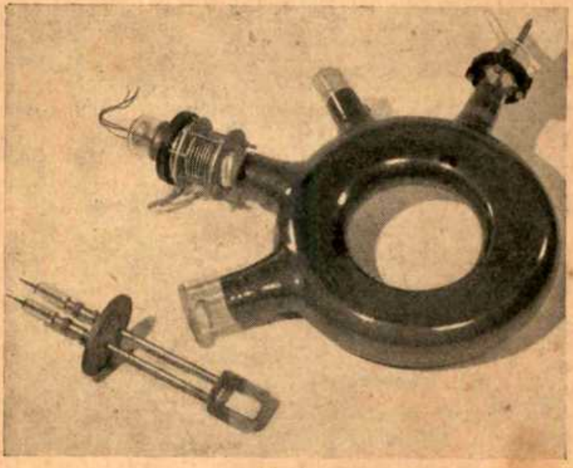

Fig. 3

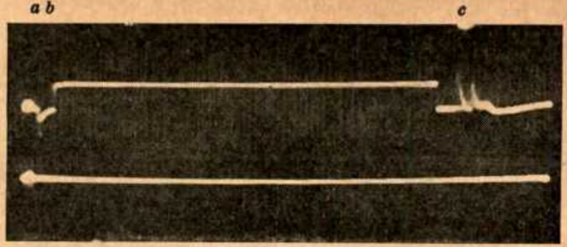

Fig. 4

field; this trace is needed when the gun is used as a target by switching off the radio-frequency at the peak field and allowing the electron orbits to expand. On the trace shown may be seen the zero field pulse, *a*, the envelope of the rectified radio-frequency accelerating voltage, *b*, and the response, *c*, from a Geiger–Müller counter placed in the γ-ray beam. The response appears as a double pulse, a phenomenon which has been already investigated on the American 70-MeV. synchrotron, which has sufficient intensity to actuate a photomultiplier tube[2].

The experimental results so far obtained with the synchrotron are qualitatively in agreement with previous results reported[1,2]. This first 30-MeV. machine will continue to be used to develop synchrotron techniques and to guide the design of the 140-MeV. and 300-MeV. synchrotrons which are being constructed. One of the later 30-MeV. machines, now in the stage of final commissioning, will be used as a nuclear physics tool by the Physics Department of the University of Glasgow. Two further machines are being built for the Medical Research Council for medical investigations. In addition, a machine has been modified to test whether a frequency-modulated synchrotron is practicable.

Acknowledgment is made of the assistance given to this project by our colleagues at the Telecommunications Research Establishment and by industrial firms and potential users of the machines. It is hoped to make full acknowledgment of these contributions in later descriptions of more specialized features of the apparatus. The work described here was carried out by the Electronics Group of the Atomic Energy Research Establishment, at the Telecommunications Research Establishment, Malvern, and acknowledgment is made to Sir John Cockcroft for permission to publish the results.

BIOLOGY IN COLONIAL UNIVERSITIES

PLANS which are in train or which have already been carried out for the setting up of university colleges in the West Indies, at Singapore, at Ibadan, Nigeria, and in the Gold Coast, as well as for the extension of Makerere College, Uganda, give point to the parallel discussions which have been going on with regard to the content and outlook of the curriculum which should be offered in these centres of higher education for Colonial people. It has been generally agreed that subjects contributing directly to human welfare should receive greater attention than has been the case in the more ancient seats of learning in Britain; it has also been generally agreed that the subjects offered should form part of some concerted scheme. With such ends in view Dr. E. B. Edney makes out a case for the setting up in Colonial universities of single departments of biology instead of separate ones for botany and zoology[1].

Dr. Edney has had experience of Colonial education as tutor in biology at Makerere College. In his article he directs attention to the fact that many problems coming under botany and zoology are really biological; the biological approach to them is more vital and organic. For students working to 'pass' standards—and these for some time to come will be the great majority at Colonial universities—botany and zoology as taught at present, he maintains, are too morphological. One reason for this is that all human physiology is taken over by the medical schools.

So far as Colonial universities are concerned, the question may be debated in relation to three main functions: the training of teachers, applied scientists, and research workers. As regards the first it is suggested that at the school stage the aim should be to develop a biological approach built around the concept of the organism in relation to its environment. As for applied scientists, whether agriculturists, entomologists or medical practitioners, problems in the field are always biological. Training, therefore, should include instruction in biological relationships. Under present conditions such training is given only as part of vocational work.

In relation to research, Dr. Edney maintains that, in any event, a biological approach could not have a stifling effect, and that the association of workers interested in both plant and animal biology should prove a fruitful one. Fields of research like genetics, cytology and ecology are not either purely botanical or zoological, yet they are as important and attractive as any others. It might be objected that the biological approach is too general and superficial, and that concentration on the morphological and systematic aspects of the subject is necessary for developing accuracy and an appreciation of scientific discipline. The author admits that the subject of biology is far too wide to be covered adequately in a course of two or three years, but he sees no reason why accurate and painstaking work should not be done in fields which are essentially biological, while at the same time giving due weight to considerations which are chiefly morphological.

If it is agreed that the biological approach is of value, the question remains whether the subject should be presented by two separate departments or one. For a number of reasons Dr. Edney holds that the latter would be preferable. Existing departments of zoology and botany have their own distinctive flavours; while as regards examinations, if for the new Colonial universities they are to continue to be directed from London, a single department of biology would find it easier to devise and gain acceptance for its own syllabus. Where new universities are being founded, the setting up of a department of biology would be comparatively easy; where separate departments for botany and zoology already are in being, it might be advisable to allow them to continue, while working progressively towards closer union.

A point not touched on by Dr. Edney is the question of staffing. The supply of men of science with a genuine biological point of view is small and it is not likely rapidly to increase. To present at university standard a syllabus of the type envisaged would require the close co-operation of several men of science. While that would be highly desirable in itself it would not be easy to achieve. At the same time, a demand for biologists, as distinct from botanists and zoologists, would have repercussions on the universities in Britain which in the long run would be likely to be salutary.

As an appendix to his article, Dr. Edney has drawn up a three-year curriculum in biology to pass-degree standard, which may be obtained on application.

EDUCATION IN MYCOLOGY

THE first duty of Prof. A. E. Muskett as president of the British Mycological Society for the ensuing year was to preside at the discussions of the Society on "Mycological Education" at its meeting on January 31. In the first paper of the session, "The Society and Mycological Education", Dr. G. C. Ainsworth reminded us that mycological education is implicit in many of the activities of the Society, not the least of these being the annual foray where amateur and professional mycologists forgather for a week of intensive study of fungi collected on daily excursions. This club meeting has done much to keep alive the "tradition of species". By its report on "The Need for Encouraging the Study of Systematic Mycology in England and Wales" printed, but not published, in 1944, and by its subsequent report on "The Teaching of Mycology" printed in 1946, but again not published, the Society focused attention on the dearth of trained mycologists and of systematists in particular, and on the need for detailed consideration of, and early action to secure, the adequate training of mycologists in the diverse fields in which present-day conditions require their services. The discussion afforded the exchange of views on the question of mycological education between mycologists of widely different interests.

Admitting that the topic of education for a specific career is always a difficult subject to review, Dr. W. G. Keyworth, in presenting the case of "Mycology for the Plant Pathologist", outlined the present course of training of a plant pathologist during the study for his initial degree. Here mycology is treated in the same way as other aspects of botany, emphasis being placed on those families showing features of taxonomic interest. Research on a specific and often rather limited field of investigation usually followed before the plant pathologist embarked on his career as an adviser or as a research worker. Valuable as the present system is, Dr. Keyworth considers that continued study of general mycology after taking a first degree is of paramount importance. This study should not only include pathogenic but also saprophytic fungi, should involve a consideration of the Fungi Imperfecti, should deal with the study of the fungi *in vivo* and *in vitro*, and should include an adequate treatment of the taxonomy of fungi. Thereafter, and before commencing professional duties, the plant pathologist destined to become an adviser might gain experience in field recognition of diseases at an advisory centre, and the plant pathologist following research work as a career might gain experience in research methods and technique as applied to pathogenic fungi. Dr. Keyworth concluded by suggesting that postgraduate courses should be instituted, and that these might well lead to a diploma or to a higher degree which could be the accepted hallmark of a sound preliminary training.

The absence of courses which completely cover the requirements of industrial microbiologists was emphasized by Dr. F. D. Armitage during his paper on "Mycology and the Industrial Microbiologist". Certain microfungi are studied as examples of moulds in courses of bacteriology, but to obtain a working knowledge of systematic mycology the microbiologist must depend on private reading of current literature —a task almost impossible without some expert guidance. He suggested that the Society might use its influence to create a school of mycology which would develop a course suitable for mycologists in industry, paying particular attention to mycological technique, to the maintenance of culture collections, to the sampling methods applied to mycological analysis, to the study of inhibitors and to the principles of taxonomy. Failing this, the Society might organise, and later publish, a series of lectures designed for those commencing the study of microfungi. He was certain sound mycological education is a vital problem at the present time.

During his paper on "Mycology for the Medical Practitioner", Dr. I. Martin Scott suggested that the practitioner's lack of intimate knowledge of this branch of science was due to the overloaded curriculum of the present degree and to the lack of facilities for graduate studies. Normally only a single lecture is devoted to pathogenic fungi during undergraduate courses, and in public health studies only a short course on medical mycology is available. The remedies are obvious: future undergraduates should receive systematic instruction in mycology, as they do now in bacteriology, and graduate schools for further study and for research should be established. Close collaboration between medical practitioners and mycologists is essential in this field.

The case for "Mycology for the Amateur" was ably presented by Mr. J. M. B. King, who stated that the Society offers the best place for the amateur, who takes his mycology seriously, to obtain that advice and guidance which the personal experience of its members, obtained by the study of fungi in the field, can give. The Society could further aid the amateur by sponsoring books written in as non-technical a language as possible containing adequate keys, colour charts and fully documented glossaries of necessary technical terms. He believed that periodic publication in its *Transactions* of articles dealing with the fundamental features of fungal structure, with the principles of classification and with taxonomic problems would be appreciated. Efforts might be made to increase the number of forays and of meetings of general interest, some of which might be demonstrations of named specimens similar to that recently held.

Dealing with "Mycology and the Universities", Prof. C. G. C. Chesters stated that the orthodox training in mycology was obtained within the scope of an honours degree in botany, the fungi being treated as a section of the Thallophyta. He believed that the fungi should be removed from this phylum and might be treated as a separate discipline within the confines of botany. Since mycology must be based on a knowledge of the living fungus, collection of material in the field must play a large part in any well-balanced course, which must also include the study of the physiology, the genetics and the technique of cultivation of fungi *in vitro*. Graduate studies of a more detailed character should precede research investigations. Suggesting that there might well be a place for a more heterodox training in mycology, he outlined a course for an honours degree in which, during the years subsequent to intermediate studies, chemistry, botany (excluding the fungi) and mycology should be studied as parallel courses for two years and should be followed by a final year devoted entirely to mycology. The principles of bacteriology should be introduced during initial studies in mycology.

Mr. L. M. J. Kramer, speaking on "Mycology in Relation to Schools", said that it was mainly during study for the higher school certificate or the university entrance examinations that the implications of mycology and the future openings for those able to undertake the necessary training could be presented to the scholars. Teachers would appreciate articles on simple laboratory exercises, on current trends in mycological studies and on openings for mycologists, as well as details of the necessary training, in such journals as the *School Science Review*.

In the discussion which followed the papers, Dr. Wilkins supported the separation of mycology from botany and hoped that the Society might influence university opinion to recognize mycology as a special subject for study. Dr. J. Ramsbottom considered that Mr. Kramer's suggestion that there was a lack of trained science teachers raised an important topic and stated that, while he would not enter the argument for or against mycology being taught as a discipline separate from botany, it was essential to realize the great development of mycology during the past few years. Progress in teaching industrial mycology is slow at present but nothing can stop the development of this line of study. The hope for medical mycology lies in the fullest co-operation of the mycologist and practitioner. He believed the possibility of a bulletin for amateurs sponsored by the Society might be considered. Mr. Large pointed out that plant pathologists had to be more than professional mycologists and that there was a decided lack of good drawings and simple descriptions of fungi. Dr. Wood was against any separation of botany and mycology and emphasized that plant pathologists had to be botanists. Dr. Cook believed that botany was outgrowing itself, that the difference between green plants and fungi was fundamental and that there was a place for a specialized mycology course following a general degree with botany as one of its subjects. Dr. Prentice deplored early specialization and considered that specialized graduate studies should follow a liberal first degree course. Dr. Keyworth thought a degree in botany was of fundamental value and that the necessity of a lengthened period of training by the introduction of postgraduate courses must be considered.

Reviewing the papers and the subsequent discussion, Prof. C. T. Ingold reminded members that the Society had developed from a field club to assume the lead in mycological thought in Great Britain without losing the essential characters of a field club. Its reports demonstrate its vital interest in adequate provision for mycological education and its encouragement of taxonomic studies. Believing that the greatest weight should be placed on special postgraduate courses, Prof. Ingold referred to the present contribution of individual departments and suggested that industrial mycology might be established at technical colleges and, when medical education is reorganised, a place should be found for medical mycology. He considered that fungi should be treated outside the Thallophyta and that a reunion of bacteriology and mycology would be advantageous. Additional literature on the systematic side is urgently required. Prof. Ingold concluded by suggesting that the Committee of the Society which dealt with the teaching of mycology might continue its deliberations in the light of these discussions and might consider the institution of special series of lectures on mycological topics.

CHARLES G. C. CHESTERS

A TRIBUTE OF INDUSTRY TO SCIENCE

A SPECIAL meeting of the Industrial Research Committee of the Federation of British Industries was held at the Royal Institution on March 19 in honour of Sir Robert Robinson and Sir Edward Appleton, who received the Nobel Prizes in 1947 for Chemistry and for Physics, respectively. Sir Frederick Bain, who presided, pointed out that not since 1904 had the prizes for chemistry and physics both come to Great Britain undivided and undisputed, although since 1901 Britain has had no less than thirty-six Nobel Prize awards in the five different categories. He described the meeting as a whole-hearted demonstration by British industry of pleasure at this authoritative recognition of the work of Robinson and Appleton, who now shared the distinction of Sir William Ramsay and Lord Rayleigh in 1904, and also a sincere recognition of what industry owes to science as represented by them. Sir Frederick said that he had been privileged to work intimately both with Sir Robert and Sir Edward, and that during the War we had learned how the scientist and industrialist could work together for a common objective. Great scientists could be effective men of affairs, and through the example and devotion of men like Robinson and Appleton, Britain had become, in war as in peace, not only a country of the questing mind and free experimental approach but also, above all, a place for sharing ideas, improvisation in emergency and effectiveness in application of scientific work.

Sir Robert Robinson, in a brief address on the "Scope of Organic Chemistry", referred to the way in which contact with industry has enriched our knowledge of organic chemistry, to the great stimulus which the study of complex molecules has given to organic chemistry and conversely to the contribution of organic chemistry to the development of the biological sciences. After referring to the opportunities for co-operation between different scientific workers afforded by such fields as catalysis and polymerization, and to the evolution in the last twenty years of the industry of aliphatic chemicals, Sir Robert stressed the national importance of organic chemical industry. In this connexion he urged the extension of facilities for research in organic chemistry and stressed the function of the universities in training research workers. For that function to be discharged effectively, parallel with the growth of industrial research laboratories and the expansion of technical colleges, there should be higher salaries for science teachers and the enlarging and modernization of university departments.

Sir Edward Appleton's address, "The Scientist in Industry", discussed in greater detail some aspects of the balance of the scientific effort of Britain now that it has recovered from the distortion due to our war effort. That effort, and particularly the development of the atom bomb, illustrated the rapidly increasing momentum of scientific and technical progress and the way in which the lag between scientific discovery and its practical application can be decreased. Sir Edward, emphasizing the importance of avoiding any segregation of our research effort whether in the universities, in Government departments, or in industry, said that while in the university, where fundamental scientific research is mainly conducted, the only discipline is that of science itself, in Government and industrial research there is the further discipline of specified objectives, wide though these may be. The more liberally the restrictions imposed by the nature of the organisations which such scientific workers serve are interpreted, the better the scientific health of the men who work in them. Sir Edward then spoke of the broad lines of policy pursued by the Department of Scientific and Industrial Research, and of the necessity of a wise use of men of science in industry. He attributed our success in the War very largely to the mutual understanding which developed between the General Staff, the scientific workers and those responsible for production; and we need in peace the same sense of partnership between management, scientific men and other workers in industry. Commenting further on the importance of the human aspects of the scientist's work, he urged that the discipline of science should result in complete impartiality in interpretation, and that the scientific worker should make his own contribution to the simplification of managerial decision, and particularly by clarity in expounding the results of his work. He described 'operational research' as meaning the application of scientific methods to the quantitative estimation of the effect of the changes in all kinds of factors which might influence industrial efficiency; and he said that, while industry before the War had often sought in this way to obtain reliable data as a basis for executive decisions, such methods could be of particular value at the present time in enabling science to contribute effectively to the increase of national productivity. The research associations are admirably fitted for such work.

The scientific worker in industry, Sir Edward said, has three principal functions: first, to provide a scientific service for his firm or industry; secondly, to carry out research aimed at devising new or improved processes, goods and materials; and thirdly, to contribute to the world's stock of scientific knowledge. He believed that what scientific workers value most is the good opinion of their scientific colleagues, and it is impossible for them to feel they can acquire and retain this if their work is so circumscribed and limited in outlook as to cut them off entirely from the main stream of scientific progress. What matters most is not money and equipment, but men and leadership—above all, leadership which understands men.

Sir William Akers, in a tribute to Sir Robert Robinson, spoke of the extreme elegance of his methods as the distinguishing characteristic of his work on complex organic molecules ranging from the anthocyanins and alkaloids to the sterols, in which he had made organic chemistry a branch of physical chemistry. His approach and methods in dealing with a problem were of intrinsic beauty, and this elegance was matched by his personal modesty. Sir William Larke, in a tribute to Sir Edward Appleton, referred not only to his work on the exploration of the ionosphere and his contribution to the development of radar, but also to his fine and human leadership of the Department of Industrial and Scientific Research. Sir William particularly welcomed Sir Edward's reference to the importance of exposition and interpretation, and to the view of operational research as a normal function of management. It was most fitting that the meeting should be held in the Royal Institution, where Faraday and others had carried out so much work upon which industrial development was based.

A complimentary dinner was given by the Federation to the two Nobel prize-winners that evening, and there were present the Prime Minister, the Lord President of the Council, the Minister of Food, the Minister of Fuel and Power, Lord Samuel, Lord Hankey, Lord Addison, Lord Cherwell and Sir John Anderson, the High Commissioners of New Zealand, India, Canada, Australia and Eire, and many other public men. The Prime Minister proposed a toast to the two guests of honour, saying that the recognition by the Federation of British Industries of the work of these two great men of science showed that the Federation appreciates the vital necessity for Britain to use to the full the resources of science if we are to hold our own in the modern world—and, he added, we are going to hold our own. He believed that industry is more alive than ever to the value of fundamental research, and he paid a tribute to the work of the Department of Scientific and Industrial Research. He hoped that the National Development Corporation would help to fill any gaps in the development of scientific discovery to full-scale production, and while the award of the Nobel Prizes to Sir Robert Robinson and Sir Edward Appleton showed that we are recognized as in the front rank in the field of science, he believed that Britain still has an immense contribution to make to the progress of the world.

Sir John Anderson, who seconded the toast, dealt more particularly with the scientific achievements of the two prize-winners, and stressed the importance of Sir Edward Appleton's work for radar during the War, and of Sir Robert Robinson's work for the supply of drugs and medicinals in the First World War. Sir Robert's rise to fame, in fact, coincided with the rise of the organic chemical industry in Britain, and Sir John remarked that while Britain has often led the world in fundamental science, we have not been quite so good in following up fundamental discovery.

Sir Robert Robinson, in responding to the toast, paid a warm tribute to the work of the many colleagues associated with him in his researches over the last forty years, among whom Lady Robinson had already been mentioned by the Prime Minister in a charming little tribute. Sir Edward Appleton, who also replied, said that in looking back over twenty-five years of research, he could not recall any sudden flashes of insight, although there had been many exciting moments. He reminded his audience that really great achievements are sometimes accidental and unintentional, and we should not be concerned exclusively with the material consequences of science. Science enlarges men's minds and could bring home to everyone the wonder and significance of the world in which we live. Science-teaching in our schools and universities should be far more than merely vocational training. In the international sphere, science means knowledge, and knowledge means power. Like other men, the scientific worker is deeply perturbed and morally concerned about the use or misuse of scientific knowledge. Atomic energy, for example, in itself threatens no one; but the possible use of atomic energy by nations prompted by hatred, envy or fear brings a new apprehension in our lives. The problems raised by this challenge are not for the scientific worker alone, though he has a right to his own views as a man of science; and Sir Edward stoutly supported a scheme of adequate international control at the present stage of the world's moral development, even while looking forward to a world in which such control would be unnecessary.

OBITUARIES

Sir Charles Grant Robertson, C.V.O.

Sir Charles Grant Robertson, who had been principal and, after the amendment of the University Charter in 1927, vice-chancellor of the University of Birmingham from 1920 until 1938, died at his home at Ringwood in Hampshire on February 29. Born in 1869, he passed from Highgate School to Hertford College, Oxford. There he had a brilliant career, being elected a fellow of All Souls in 1893. At Oxford he earned a reputation as a distinguished historian. In 1920 he was appointed principal of the University of Birmingham, to succeed Sir Oliver Lodge, the first principal, who had retired in 1919.

On the outbreak of war in 1914, the main buildings of the University of Birmingham at Edgbaston were immediately taken over by the War Office and converted into the First Southern General Hospital, and what was left of staff and students was scattered to various crowded and inadequate quarters in the city. At the end of the War in 1918, the problem of reconstruction was immense. The buildings had to be cleared and restored to their proper functions and a battle had to be waged with the War Office for the cost of reconversion. Many temporary huts had to be erected to accommodate the flood of undergraduates surging in after demobilization, staffs had to be increased and money had to be raised. The University was heavily in debt and new and costly buildings were essential. An appeal for half a million pounds was therefore launched. The new principal used his remarkable powers of eloquent persuasion, both in public and in private, to great effect, and soon large sums came in from generous Birmingham benefactors, and some of the much-desired ideals became realities. The new Biological Block was built; to the department of chemistry was added the Hills Chemistry Block; and through the munificence of Sir Charles Hyde the Hall of Residence (Chancellor's Hall) and the Students' Union came into being. Sir Charles Grant Robertson used his organising abilities to get a better balance between the faculties by the development of the Arts side and extending the Library. A faculty of law was established, with a chair endowed by Mr. Henry Barber.

Another project dear to the heart of the principal was the building and endowment by Lady Barber, in memory of her husband, of the Barber Institute of Fine Arts. This Institute, which has a beautiful music room in addition to its picture galleries, provides the students with rare opportunities for cultural education outside the routine courses. Behind all this development was always the energetic personality of Sir Charles.

But perhaps the greatest and most far-reaching of Sir Charles' activities was his advocacy of the Hospitals Centre, with an associated medical school. For thirteen years he laboured unceasingly as chairman of the Hospitals Centre Committee with a generous, energetic and resourceful band of fellow citizens, and finally had the satisfaction of seeing the completion (or, perhaps more exactly, 'the end of the beginning') of their work in the form of the great Queen Elizabeth Hospital, in front of which extends the magnificent building of the Medical School, a visible monument to the solidarity of the University and the City. The persistent energy with which Sir Charles Grant Robertson worked for the advancement of the University of Birmingham in all its branches has left an abiding mark on the great city of whose long line of great 'peaceful invaders' he was not the least.

G. A. Shakespear

Mr. Griffith Brewer

By the death of Mr. Griffith Brewer on March 1, the fraternity of aeronautical pioneers has lost a well-beloved and much respected friend. Brewer was born in London in 1867 and was by profession a patent agent. For nearly sixty years his chief interest lay in aeronautics, and he was not only an authority on aircraft patents but also a notable balloonist and, later, an aviator who bore the distinction of being the first Englishman to fly in an aeroplane—as a passenger with Wilbur Wright in 1908. Abroad, he was perhaps best known for his work and friendship with Wilbur and Orville Wright and, in particular, for the part he played in the so-called 'Wright–Langley controversy'.

Griffith Brewer was a man of marked integrity and courage; he displayed these virtues to the full when investigating and exposing the claims made in respect of Prof. Langley's 'aerodrome' after its reconstruction and flight in 1914—claims which he regarded as damaging to the credit of the Wright brothers. He was instrumental in 1928 in obtaining the original Wright aeroplane of 1903 for exhibition in the Science Museum, London, as a further step towards securing unqualified recognition of the Wrights' achievement. This recognition is now happily established and shortly to be confirmed by the return of the machine to the United States for preservation in the National Museum at Washington. His vindication of historical truth in that issue is likely itself to pass into history. In 1913, Brewer was entrusted with the formation of the British Wright Company to administer the Wright brothers' patents in England.

Brewer obtained his pilot's licence at Dayton, Ohio; in 1933 he gained a licence for flying autogiros. He served for many years on the Council of the Royal Aeronautical Society, of which he was a past-president; and in 1912 founded the Society's Wilbur Wright Memorial Lecture. His gentle presence and kindly nature will be missed there. M. J. B. Davy

We regret to announce the following deaths:

Prof. A. S. Eve, C.B.E., F.R.S., emeritus Macdonald professor of physics in McGill University, on March 24, aged eighty-five.

Prof. M. C. Potter, emeritus professor of botany in the University of Durham since 1925, on March 9, aged eighty-nine.

NEWS and VIEWS

Sexcentenary of the University of Prague

THE decree of Charles IV, king of Bohemia, founding the Universitas Carolina, now the University of Prague, was dated April 7, 1348. Its sexcentenary was to have been celebrated by an international gathering; but events in Czechoslovakia have led to the withdrawal of acceptances of invitations by universities of Britain, on the ground that the University no longer enjoys its academic freedom. Charles' decree appointed the archbishop, Arnošt of Pardubice, as chancellor and stipulated that it should "serve the cultural needs of the Bohemian people, that they should no longer beg at foreign tables but have a worthy feast brought to their own table". At first, instruction was in Latin, and being one of the few educational centres it attracted many German and other students. During the rectorship of John Hus at the beginning of the fifteenth century, the Czechs were outvoted in administrative appointments. This led to the famous Kutná Hora decree of King Wenceslas, in 1409, giving the Czech 'nation' three votes and the others (German, Polish and Silesian) one each, an action that led to the departure of the Germans and hastened the founding of the University of Leipzig in 1411.

Religious matters often dominated university life, and many *magisters* found themselves against ecclesiastical and royal authority, especially after the advent of the Habsburg rulers in 1526. The botanist, Zaluzianský, was rector about 1600 and tried in vain to secularize the University; when the Czechs lost their independence in 1620, Ferdinand II installed Jesuit teachers and it became the Charles-Ferdinand University. A long period of stagnation followed, but eventually it regained some of its earlier significance, and during the nineteenth century several professors achieved world-wide reputations. Czech was again used by some, and in 1882 the University was divided into Czech and German institutions. These endured through the period of the first republic until Czech higher educational establishments were closed by the Nazis in 1939. The Charles University reopened in 1945 and had to cope with six years accumulation of students and with teaching staff depleted through age and executions. In the present academic year there are altogether 23,977 students (including 5,423 medical, 4,977 philosophy, 2,181 science) and provision has been made for research work in practically every subject.

Duddell Medal of the Physical Society: Dr. R. J. Van de Graaff

THE Duddell Medal for 1947 of the Physical Society has been awarded to Dr. R. J. Van de Graaff, of the Massachusetts Institute of Technology, in recognition of the invention and development of the high-voltage electrostatic generator already known by his name. To Van de Graaff belongs the credit of making a type of particle accelerator based on the simplest possible conception. Electric charge, sprayed on to a moving belt, is carried into a sphere, acting as a Faraday cage, until the potential rises to the desired value. The full potential to be applied to the particles thus exists between the sphere and the earth, and the great practical difficulty is to avoid discharges at undesired positions and corona losses. Van de Graaff overcame all these difficulties and so long ago as 1937 he exhibited at the Paris Exhibition an apparatus producing 4,000,000 volts. Sets for 10,000,000 volts have more recently been built and operated successfully. Dr. Van de Graaff will receive the Medal at a meeting of the American Physical Society in Washington, D.C., on April 29; the presentation will be made by the British Ambassador, Lord Inverchapel.

Chemistry at University College, London: Prof. E. D. Hughes

RECENTLY the Chemistry Department of University College was reinforced on the side of inorganic and physical chemistry by the addition to the staff of Dr. Kathleen Lonsdale; now organic chemistry in the Department is to be strengthened by the appointment of Prof. E. D. Hughes to the additional chair of chemistry which the Senate of the University has just created. The other professors in the Department are Prof. S. Sugden and Prof. C. K. Ingold. Prof. Hughes was originally trained in the University of Wales. His first researches were carried out during 1927–30 at Bangor under the leadership of the late Prof. Kennedy Orton and Dr. H. B. Watson. In 1930 he went to London to work with Prof. Ingold at University College, and in 1934 joined the staff of that College. There he formed an active research group, closely integrated with that of Prof. Ingold. In 1936 he received the Meldola Medal, which is awarded for the most distinguished chemical work carried out under the age of thirty. In 1943 he was appointed professor of chemistry at University College, Bangor, thus succeeding to a chair which his former master, Prof. Orton, was the first to make famous.

Prof. Hughes is distinguished for his researches on the mechanism and kinetics of organic reactions, particularly in relation to substitution and elimination. He discovered and firmly established the unimolecular forms of these reactions, and made many extensions of these basic observations, for example, to the elucidation of the multiform mechanisms of carboxyl esterification and hydrolysis, and to the clarification of the conditions for the Walden inversion. In these studies he has made considerable use of both radioactive and non-radioactive tracers: the stills at Bangor for the production of heavy oxygen are probably the most powerful in existence. His most recent work refines the concept of steric hindrance, provides direct evidence concerning the formation and stability of the nitronium ion and its role in nitration, and defines the mechanisms operative in anionotropic change. He has published more than ninety original papers.

Geography at Bedford College, London: Mr. Gordon Manley

MR. GORDON MANLEY will go to the newly created chair of geography at Bedford College, University of London, with wide experience of university life in Britain and as an acknowledged authority on climatology. Mr. Manley graduated at both the Universities of Manchester and Cambridge, where he was an exhibitioner of Gonville and Caius College, and he has held university posts successively at Birmingham, Durham—as first head of the Geography Department—and Cambridge. His interests in the meteorological aspects of snow-cover may have derived from his enthusiasm for the Pennines and the Lake District as a keen mountaineer and rock climber as well as geographer. A visit to East Greenland as a member of Mr. J. M. Wordie's expedition of 1926 confirmed these interests. More recently he has analysed long-period temperature records in the north of England and revealed the gradual warming of our winters since 1820. The close resemblance between these changes and those for Stockholm suggests that this matter is of far more than local significance. In these early records Mr. Manley sees a valuable source of information that may throw light on the greater climatic changes of the Pleistocene Ice Age. Mr. Manley is, too, a keen but balanced advocate of the geographer's contribution to meteorology. This was the theme of his second presidential address to the Royal Meteorological Society. The Buchan Prize in 1943, the Symons Lecture in 1944, and the Murchison Grant of the Royal Geographical Society in 1947, all marked Mr. Manley's contributions to climatology; but his papers also include other branches of geography, particularly the history of cartography. Mr. Manley remained at Cambridge long enough to see the University give somewhat belated recognition to meteorological studies by setting up a Meteorological Committee, of which he was the first secretary.

Iron and Steel Institute Awards

The Council of the Iron and Steel Institute has made the following awards: Bessemer Gold Medal for 1948, to Mr. W. J. Dawson, formerly of Hadfield's, Ltd., in recognition of his contributions to the development of steel castings and to the production of alloy and heat-resisting steels; Sir Robert Hadfield Medal for 1948, to Mr. A. Preece, reader in metallurgy in the University of Leeds, in recognition of his researches on the scaling and on the overheating and burning of steel; Williams Prize for 1947, to Mr. R. Fowler, of Richard Thomas and Baldwins, Ltd., for his paper on "Blowing out a Blast-Furnace", printed in the *Journal of the Iron and Steel Institute*, **155**, 513 (1947). The presentations will be made on May 5 during the annual general meeting of the Institute.

American Institute of Biological Sciences

An American Institute of Biological Sciences has recently been established. The rapid advance of the biological sciences and their impact on human welfare have created new problems relating to the development and application of those sciences. During recent years many biologists have recognized that the biological sciences suffer from the lack of a service organisation, which would help "the various biological societies to discharge more effectively those functions which are of common concern to them all, but which they cannot adequately exercise as individual societies." The new organisation is designed to fill this need as well as to serve the biological sciences in other ways. A governing board has now elected the officers and an executive committee. Recognizing the potential importance of this new undertaking for the advancement of the biological sciences, and through them for all biologists, the U.S. National Research Council has not only endorsed the programme, but has also agreed to make available the general services of the Council. As a part of the National Research Council, the Institute will also provide biologists with an agency through which they can maintain close relations with governmental activities and with other fields of science represented within the Council.

The Fall Webworm of North America in Europe

Dr. Paul Surányi, University of Agricultural Sciences, Budapest, states in a letter that the first specimen of the moth of fall webworm (*Hyphantria cunea* Drury) to be caught in Europe was found in the vicinity of the Danubian Free Port of Budapest in 1940. Hitherto it has not been observed outside the United States and Canada. The way it has increased shows that its caterpillar has found very favourable conditions of life in Europe. Nests of the caterpillars were first observed in 1943; since then it has increased rapidly, and during 1945–46 it did considerable damage in orchards and on various trees. It was distributed over a semicircular area with a diameter of 80 km. in 1946, which has now increased to 200 km. Indeed, this destructive insect has overrun two-thirds of Hungary, has reached the borders of Czechoslovakia and Yugoslavia, and is approaching those of Austria and Rumania. North of Budapest it is seldom observed, due probably to the prevailing north to north-west wind. Its favourite feeding-plants—the same as in North America—are *Acer negundo* L. and *Morus alba* L., from the latter of which it strips the leaves in groves and along the highways. But it feeds on all fruit-bearing and garden trees, and—what is much more dangerous—it has established itself also in the woods. Fifty-eight species belonging to different genera are known to be food plants; they include oak (*Quercus* spp.), alder (*Alnus glutinosa L.*), black locust, (*Robinia pseudacacia* L.), common stinging nettle (*Urtica dioica* L.), cabbage (*Brassica oleracea* L.), and also horseradish (*Armoracia lapathifolia* Gilibi). Two generations of the fall webworm normally hatch in a year. Its swift spread seems to be due not only to suitable conditions, but also to the fact that, so far as Dr. Surányi's experience goes, the caterpillars are seldom attacked by European parasites.

Mechanics of Packings of Granular Material

In view of the many technological fields where an understanding of the properties of granular materials is fundamental, it is surprising that there has been little systematic investigation, the present inchoate body of knowledge being derived from *ad hoc* studies. In reviewing the more recent literature, D. R. Hudson (*Machinery*, **70**, 617, 681; 1947) discusses work on packings of material in bulk carried out by investigators in the fields of geology, fuel technology, the ceramic industry, civil and chemical engineering, and powder metallurgy. This widespread interest may account partly for the diffuse study in industrial research. On the academic side the present preoccupation with the fine-structure of matter has led to the neglect of Osborne Reynolds' pioneer work on packings, undertaken in the 1890's in an attempt to provide a mechanical explanation of the universe.

Hudson's review is more concerned with the structure and characteristics of a compacted granular bed—the voidage and number of interparticle contacts and their dependence on particle size and size distribution, the relative size and the shape of the container—than with the effect on the structure of deformation of the packing, which is of especial importance in earth pressure theory, in the study of handling and conveying mechanisms and in the design of hoppers, bunkers and silos, where Reynolds' principle of dilatancy provides a key to the construction of force diagrams. Nevertheless, Hudson emphasizes the complex character of packings as opposed to the ordered structures of crystallography and the random assemblies of statistical mechanics, and implies the impossibility of deriving a satisfactory theory of packings as an extension of the geometry of ideal ordered or disordered arrangements of equal spheres.

Foraminifera

To British marine zoologists, more particularly those dealing with the North Sea area, Hans Högland's work on the foraminifera in the Gullmar Fjord and the Skagerak (*Zool. Bidrag f. Uppsala*, **26**; 1947) should prove very useful. While it includes only thirteen families of the Foraminifera it has reached formidable size, for in it are discussed in detail 133 species and varieties, and the remaining families are likely to contain nearly as many forms. It is fortunate that the author has had access to Goës' material, for it formed the basis of our knowledge of the Foraminifera in this area. Since the publication of Goës' work more than fifty years ago, a great deal has been done on this group with much alteration of classification and taxonomy. In classification, Högland has adopted a somewhat conservative attitude and has based his upon that of Cushman (1933), but he has been more drastic in the matter of nomenclature. Where the data appeared adequate the work has been carried out quantitatively, and here striking differences resulting from various collecting techniques are manifest. As an example, we have one form, *Bulimina fusiformis*, where the core sampler gave a total of 5,500 specimens and the corresponding sledge-net sample gave only thirty. It is interesting to note that the author was attracted to the study of this group from the ecological point of view, but soon realized that ecology must be based upon sound identification and taxonomy: hence the 32 splendid plates and the 303 figures which illustrate the range of variation within what the author regards as valid species.

Scientific Research in India

A REPORT has been issued, in the *Proceedings of the National Institute of Sciences of India* (**11**, Pt. 4, 161–370), of a symposium on the centralization of scientific research in India, held on July 23, 1945, which was opened by the president of the Institute, Mr. D. N. Wadia. Mr. Wadia, after referring to the necessity of taking into account the effect of a central policy on the work of various scientific institutions in India, emphasized the benefits likely to accrue from a central organisation for scientific research. Central direction should not involve too much interference or loss of independence in the pursuit of science. Dr. J. A. Dunn supported the liaison and co-ordination of research by a single member and department of a central government as the only course which could be wisely pursued, but he was not in favour of the whole of the country's research being brought under one department. He outlined a scheme for a central council for scientific and industrial research, with provincial and State councils, a committee of central scientific departments and other boards and committees as required. Dr. A. C. Ukil advocated the co-ordination of researches but without power of interference with the findings of the National Research Council, which should be the supreme central body to organise research throughout the country; no Government department, he said, should be allowed to maintain its separate research section, independent of the guidance of that Council.

Prof. J. N. Mukherjee also emphasized that the different units dealing with various aspects of research need not all be under one authority; centralization of scientific research should not mean centralized control under one government department. The autonomy of universities and other non-official institutions should not be circumscribed. Prof. M. N. Saha strongly supported Prof. Hill's scheme, as did Prof. P. C. Mahalanobis, with some warning on the danger of bureaucracy and departmentalism creeping in. He urged that the National Institute should press for the fullest possible association with the work of the proposed department of the learned societies, universities and scientific institutions. Prof. S. P. Agharkar thought that the real difficulties in India were encountered at the policy-making level. Dr. G. J. Fowler set forth points for and against centralization and urged the need for care lest organisation crippled individual initiative. Dr. Nazir Ahmad indicated some practical difficulties, but supported the co-ordination of research so as to avoid overlapping, to accelerate the pace of research and to use and to train talent to the best advantage. Dr. J. N. Roy considered that the National Institute of Sciences should concern itself solely with the availability of adequate funds for scientific research, and that the question of organisation was outside its sphere. A report of the symposium is being sent to all Departments of the Government of India with an expression of opinion from the fellows of the Institute as to the necessity of there being one Department of the Government of India concerned with the formulation of policy, determination of priority and administration of all funds earmarked for scientific research.

Radio and Electrical Research in Canada

THE National Research Council of Canada has announced the formation of a Radio and Electrical Engineering Division under Mr. B. G. Ballard. This new Division is a consolidation of work formerly carried on in the Division of Physics and Electrical Engineering, and has become necessary on account of the great expansion of research activities in the fields of electronics and electrical engineering consequent upon the advances in radio and related techniques during recent years. There are at present some 230 members of staff in the Division, including about fifty scientific personnel, and their work includes various aspects of radar, radio-physics, high-voltage electrical engineering, and the general application of electronics for military as well as for civil purposes.

Mr. Ballard, the new director of the Division, after graduating from Queen's University, Canada, obtained five years industrial experience with the Westinghouse Electric and Manufacturing Co. at East Pittsburgh. He joined the staff of the National Research Council in 1930, and has been engaged continuously in radio and electrical engineering research. His activities during the War were largely devoted to the development of mine-sweepers for enemy magnetic mines and the protection of ships against these mines; in recognition of his contributions in this field, Mr. Ballard was made an O.B.E. in 1946.

Lens-cleaning Tissues

Users of optical instruments will be interested in details just issued by Messrs. J. Barcham Green, Ltd., the well-known makers of specialty hand-made papers, of their "105 Lens Tissue". It is claimed that this tissue has a particularly high strength, and yet is thin, light and almost fluff-free. It absorbs moisture and oil films readily, and special precautions are taken to exclude grit and similar impurities. Its bulking properties are evident from the fact that 500 sheets make a pack 1 in. thick and weigh less than 10 per cent of the weight of the same area of an ordinary writing paper. A 'near miss' from perfection is claimed; however, since (according to the leaflet) it has been possible to achieve the long-sought ideal of a *p*H value of 7·0, this claim must be regarded as modest, in one respect at least.

University College, Leicester: Appointments

The Council of University College, Leicester, has announced the following appointments: Dr. A. G. Pool, senior lecturer in economics in the University of Sheffield, to the new chair of economics at the College; Dr. Z. P. Dienes, assistant lecturer in mathematics in the University of Manchester, to a lectureship in mathematics.

Physical Society's Exhibition

The thirty-second Exhibition of Scientific Instruments and Apparatus, organised by the Physical Society, will be held during April 6–9 at the Imperial College of Science and Technology, London. Discourses will be delivered on three evenings at 6.45 p.m. as follows: Tuesday (April 6), "Studio Acoustics", by H. L. Kirke (British Broadcasting Corporation); Wednesday (April 7), "Low Temperature Physics", by Dr. K. Mendelssohn (Clarendon Laboratory, Oxford); Thursday (April 8), "The Reflecting Microscope", by Dr. C. R. Burch, W. J. Bates and Mr. K. W. Keohane (University of Bristol). Films will be shown on each of the four days: "Atomic Physics" (including Friday, April 9, at 6.45 p.m.); "Physics and the Film" by the British Kinematographic Society. The Exhibition will be open at the following times: April 6, 2 p.m.–9 p.m.; April 7–9, 10 a.m.–1 p.m., 2 p.m.–8 p.m. Admission is by ticket only. Catalogues are now available.

Announcements

M. Charles Dufraisse has been elected a member of the Paris Academy of Sciences in the Section of Chemistry, in succession to the late M. Robert Lespieau.

Prof. W. T. Astbury, professor of biomolecular structure in the University of Leeds, will give the Silvanus Thompson Memorial Lecture of the British Institute of Radiology on April 16 at 8 p.m. in the Reid-Knox Hall at 32 Welbeck Street, London, W.1. The title of his address will be "The Structure of Biological Tissues as Revealed by X-Ray Diffraction Analysis and Electron Microscopy".

Lord Portal of Hungerford, controller of production (atomic energy) in the Ministry of Supply, has completed his work for the production organisation and its relation with research, both at the Atomic Energy Research Establishment, Harwell, and elsewhere. He has agreed, however, to continue to act on a part-time basis, without salary, for another year.

A conference on "The Human Factor in Industry" has been arranged by the British Association and will be held at Leamington Spa in the afternoon and evening of Saturday, May 8. Sir Henry Tizard, president of the Association and chairman of the Advisory Council on Scientific Policy, will preside at the first session, and Sir George Schuster, chairman of the Industrial Productivity Committee's Panel on Human Factors, will occupy the chair at the second. The conference will be open, without charge, to all who are interested. Further particulars will be available in due course by application to the Secretary, British Association, Burlington House, Piccadilly, W.1.

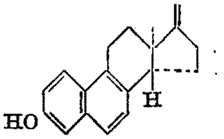
The Botanical Society of the British Isles is holding a conference on "The Study of Critical British Groups" in the Royal Horticultural Society's New Hall, Westminster, S.W.1, during April 9–10. The meeting will be held under the presidency of Mr. J. S. L. Gilmour. Further particulars can be obtained from Miss M. S. Campbell, c/o Department of Botany, British Museum (Natural History), Cromwell Road, London, S.W.7.

The Council of the Chemical Society will award grants from its research fund in June next. Applications, to be made on forms obtainable from the General Secretary, must be received on or before May 10. Applications from fellows of the Society will receive prior consideration. Attention is directed to the fact that the income arising from the donation of the Worshipful Company of Goldsmiths is principally devoted to the encouragement of research in inorganic and metallurgical chemistry, and that the income from the Perkin Memorial Fund is to be applied to investigations relating to problems connected with the coal tar and allied industries.

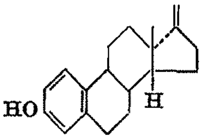
In the article in *Nature* (**160**, 250; 1947) giving an account of the International Conference on the "Emission Spectra of the Night Sky and Auroras" that was held in the rooms of the Royal Society, Burlington House, last July, it was mentioned that the papers read would probably be published in the "Reports on Progress in Physics". Pressure on space, however, prevents this, and the Physical Society has arranged for separate publication.

Prof. W. von Buddenbrock, (16) Fronhausen/L., Talstrasse 10, U.S. Zone, Germany, is asking for reprints of papers, to enable him to proceed with the preparation of vols. 3 and 4 of his "Grundriss der vergleichenden Physiologie". It is intended to translate the work into English.

Errata. Referring to the communication "The *C*/*D* Ring Union in Œstrone and Equilenin" in *Nature* of March 20, p. 434, Dr. W. Klyne states that formulæ V and VII should have been as follow and not as shown:



V. 13-*iso*, 14-*iso*



VII.

Electrical Conductivity of the Ionospheric D-Layer

RECENTLY, D. F. Martyn[1] has suggested that electric currents in the *D*-layer of the ionosphere must make a contribution to the solar and lunar geomagnetic variations roughly equal to that of the *E*- and *F*-layers. Since theoretical work on atmospheric tides suggests that the tidal motions tend to increase with height, the electric forces causing the currents can scarcely be greater in the *D*-layer than in the *E*- and *F*-layers. Hence Martyn's suggestion implies that the integral conductivity of the *D*-layer must be at least as big as that of the *E*- and *F*-layers combined. This appears to us to be improbable.

The integral conductivity of the *E*- and *F*-layers combined[2] is of order $2 \times 10^{-8} - 10^{-7}$ E.M.U. If electrons in the *D*-layer (taken to be at about 65 km.) were to produce an integral conductivity of this order, they would have to number several million per cm.^{3}. This is, of course, an impossibly high figure: to produce only a reasonable degree of attenuation in waves passing through the layer, only a few hundred electrons can be present per cm.^{3}.

If ions in the *D*-layer produced a similar conductivity, there would have to be at least 3×10^9 of them per cm.^{3}. This estimate, though large, is easily seen to be correct in order of magnitude; the ion conductivity, for a given number of ions, varies inversely as the gas-density between the *D*- and *E*-layers (that is, about in the ratio 1 : 1,000); the *D*-layer is narrower than *E*; and the *F*-layer possesses a larger conductivity than *E* unless negative ions are numerous in the latter. A density of 3×10^9 ions per cm.^{3} is difficult to reconcile with only a few hundred electrons per cm.^{3}; Massey and Bates' work on the *E*-layer[3] suggests that there can scarcely be as many as 1,000 negative ions per electron in the *D*-layer. Moreover, 3×10^9 ions per cm.^{3} are enough to reflect waves of wave-length 150 m., and to attenuate waves of wave-length greater than 35 m. to less than a tenth of their strength each time they pass through the *D*-layer. This, then, rules out the possibility of a layer of the required conductivity existing at the assumed height of the *D*-layer, that is, at about 65 km.

There remains the possibility that the conducting layer exists at a greater height, though still definitely below the *E*-layer. To get reasonable values for the attenuation of 200-m. waves the conducting layer must be at a height of more than 80 km.; if in addition the ratio of the numbers of negative ions and electrons is not to exceed 1,000 : 1, the layer must be at least at a height of 95–100 km. Such a height is not far from that of the *E*-layer, and since there are likely to be far fewer than 1,000 negative ions per electron at this level, even this height is likely to be an under-estimate. It appears, therefore, that a layer of the required conductivity can scarcely exist below the *E*-layer.

Frequency Variation of the Intensity of Cosmic Radio Noise

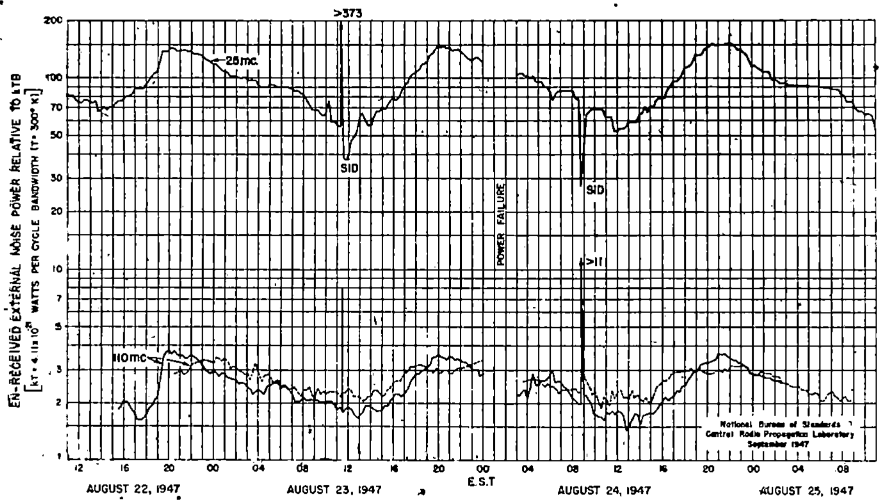
THE intensity of cosmic radio noise (as received on horizontal half-wave dipole antennæ one quarter wave-length above ground) has been measured at 25 Mc. and 110 Mc. by H. V. Cottony, W. Q. Crichlow, J. W. Herbstreit and J. R. Johler at the Central Radio Propagation Laboratory, National Bureau of Standards, using identical noise diode calibration methods. The use of similar antennæ on the two frequencies ensured that comparable weights would be given the cosmic radio noise arriving from various directions in space. Results of these measurements are shown in the accompanying graph in terms of an external noise factor $\overline{EN}^1$. Results are given on 110 Mc. for antennæ oriented both normal to and parallel to the geographic meridian. These have somewhat different diurnal patterns which compare favourably with the calculated patterns obtained when the cosmic radio noise intensity contours obtained by Reber[2], using highly directional antennæ, are appropriately integrated over the two broad directivity patterns of the dipole antennæ.

After allowing for the portion of the external noise energy radiated from the ground at an assumed temperature of 300° K., and on the assumption that the effective temperature of outer space (weighted in various directions by the dipole directivity) varies in accordance with some power of the frequency, the following expressions have been derived from these measurements for the maximum and minimum external cosmic radio noise factors corresponding to reception at this latitude on half-wave antennæ, one quarter wave-length above a perfectly reflecting ground:

$$\overline{EN}' = 4 \cdot 40 \times 10^5 \, f_{\text{Mc.}}^{-2 \cdot 41} \text{ maximum;}$$
$$\overline{EN}' = 1 \cdot 58 \times 10^5 \, f_{\text{Mc.}}^{-2 \cdot 41} \text{ minimum.}$$

Since the effect of absorption in the earth's ionosphere would be expected to be negligible on both 25 and 110 Mc. at night and on 110 Mc. both day and night, the exponent in the above two expressions was derived from the averages of the maximum values for the three nights, while the ratio of maximum to minimum noise was determined from the 110-Mc. measurements. The above expressions having been obtained in such a way as to minimize the effects of both ground and ionospheric absorption, they provide a direct measure of the variation of the mean cosmic radio noise arriving from outer space as a function of frequency. Thus this incident noise is seen to be proportional to $f_{\text{Mc.}}^{-0 \cdot 41}$, after allowance is made for the frequency-squared factor arising from the relative absorbing areas of the two antennæ. The absolute accuracy of the measurements on both frequencies is such that the first significant figure in the above exponent is considered to be accurate while the second is doubtful.

Also shown in these measurements is the occurrence of several short-time bursts of very strong noise radiation which occurred at times when sudden ionosphere disturbances were reported[3]. During the first of these, a burst of radio noise presumably of solar origin occurred on both 25 and 110 Mc. at the onset, followed, on 25 Mc. only, by a period of extraordinarily reduced external noise. In the second, the sudden ionospheric disturbance and reduced external noise on 25 Mc. commenced approximately 7½ min.



EXTERNAL NOISE RECEIVED ON HORIZONTAL HALF-WAVE DIPOLES A QUARTER WAVE-LENGTH ABOVE GROUND, AT STERLING, VA., LAT. 38° 59′ N., LONG. 77° 28′ W.

Approximate characteristics, $\sigma = 2 \times 10^{-14}$, $\varepsilon = 4$. Full line, dipole in east–west plane; broken line, dipole in north–south plane. *SID*, sudden ionospheric disturbances

before the radio noise burst, similar to the phenomena described by Hey, Parsons and Phillips[4].

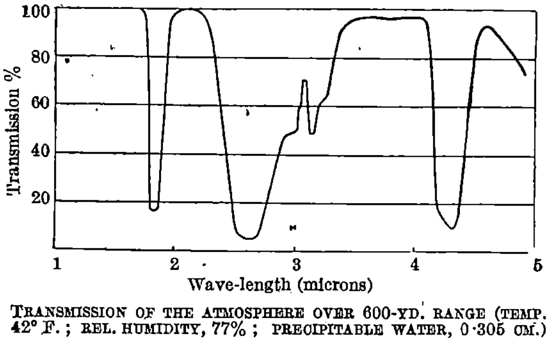
Transmission of the Atmosphere in the 1–5 Micron Region

THE most comprehensive published data available for the transmission of the atmosphere in the infra-red region is that of Fowle[1], whose results were obtained over comparatively short paths (maximum 127 yards) in the laboratory. In spite of the short path, no region clear of considerable absorption was reported between 2·1 and 8·5 microns. It may be of interest to record preliminary field results obtained during work at this Laboratory in the 1–5 micron region using the greatly improved apparatus now available.



TRANSMISSION OF THE ATMOSPHERE OVER 600-YD. RANGE (TEMP. 42° F.; REL. HUMIDITY, 77%; PRECIPITABLE WATER, 0·305 CM.)

The measurements were made using a source and spectrometer separated by a 600-yard range. The source consisted of a Nernst filament at the focus of a 2-ft. focal-length parabolic mirror of 2-ft. diameter. A mirror system of 10-ft. focal-length served as collector unit for the spectrometer. The latter was a Littrow arrangement with a 30° rocksalt prism. A Hilger – Schwarz thermopile was used as detector in conjunction with a General Motors D.C. amplifier[2]. Amplifier output was displayed on an Evershed and Vignoles 5-mA. double-pen recorder, one pen of which was used for wave-length calibration marks. To obtain the transmission curve, comparison was made between emission curves of the Nernst filament obtained over a short range (5 ft.) and over the 600-yd. range. In calculating percentage transmission, it was assumed that the value at 2·2 microns was 100 per cent[1].

A typical curve is reproduced herewith. It will be seen that, in particular, a region of high transmission exists between 3 and 4 microns. Fowle's figure for 3·5 microns is about 65 per cent transmission (127 yards). Our results were obtained in what was intended to be only a preliminary investigation; but they are considered quite adequate to show that transmission in the 3·5-micron region is comparable with that at 2·2 microns.

Spin-Dependence of Magnetic Dipole Gamma Radiation and the Nuclear Level Scheme of Pb^{208}

Hulme, Mott, Oppenheimer and Taylor[1] remarked that a γ-ray due to a transition between levels of the same parity may be a mixture of magnetic dipole and electric quadripole radiations. This is possible when the change ΔI in the quantum number I for the total nuclear spin is ± 1 or 0. The relative proportions in the mixture will depend on the structure of the nucleus. For $\Delta I = \pm 2$, no parity change, magnetic dipole radiation is forbidden and nearly pure electric quadripole radiation will be emitted. An exception occurs if the spin change is $1 \longleftrightarrow 0$, when the radiation must be pure magnetic dipole.

The presence of a high proportion of magnetic dipole radiation will give an abnormally large coefficient α_K of internal conversion in the K-shell.

α_K may approach the value for pure magnetic dipole radiation, which is roughly three times that for pure electric quadripole radiation of the same quantum energy $h\nu$, if less than 0·5 MeV.

The classification of γ-rays by the proportion of magnetic dipole radiation may prove useful in assigning quantum numbers I to the upper levels of nuclei when estimates of α_K are available.

In the case of Pb^{208}, it is clear from the photoelectron spectrum of Thibaud[2] that the M γ-ray of $ThC'' \rightarrow Pb$ of 582 ekV. has an intensity about three times that of the L γ-ray of 510 ekV., and yet their internal conversion lines have similar strengths. Measurements made with D. G. E. Martin[3] have shown that for both the L and the G rays (277 ekV.) α_K is near the theoretical value for pure magnetic dipole radiation, whereas for the M γ-ray it is much lower and in rough agreement with the pure electric quadripole value.

The contrast is striking and can scarcely be due to the highly converted G and L rays arising from $1 \leftrightarrow 0$ transitions.

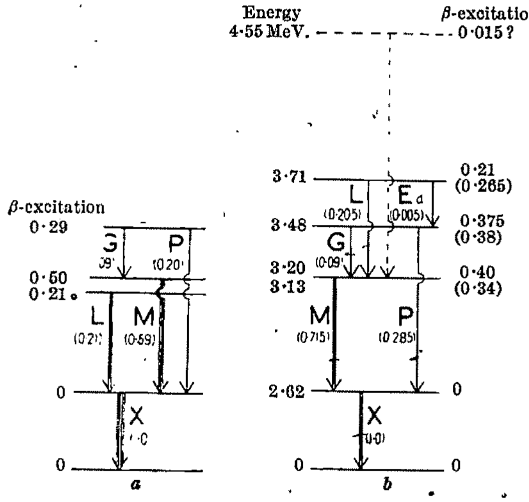

Fig. 1. LEVEL SCHEMES FOR Pb^{208} SHOWING THE NUMBER OF TRANSITIONS PER DISINTEGRATION OF THE MAIN γ-RAYS

In Fig. 1 are two level schemes for Pb^{208} (thorium D) compatible with the uncertain evidence on the γ-ray intensities which, for the P ray (859 ekV.), are taken from the data of Johansson[4]. A decision between the two schemes may be based on further evidence provided by the shape and end-point of the nuclear β-spectrum of $ThC'' \rightarrow D$.

We can calculate the end-points of the partial β-spectra which should excite the levels in Fig. 1 if we take the energy difference between the ground-states of ThC″ and Pb^{208} to be 4·995 MeV., from the known α-ray energies and the value 2·2505 MeV. for the β-ray energy of $ThC \rightarrow C'$. For the 3·204 MeV. level, for example, the β end-point is at 1·791 MeV.

Using these end-points, we get the theoretical composite β-spectra in Fig. 2. Curve (1) is for scheme (*a*), and curves (2) and (3) are for (*b*), omitting the β-spectrum to the 4·55 MeV.-level. In curve (3) the G and L γ-rays are given higher intensities of 0·10 and 0·26, with the β-excitations shown in brackets. The ordinates N/N_1 give the ratio of the number of β-rays between ε and $\varepsilon + d\varepsilon$ to the number for a single allowed transition with end-point at 1·791 MeV. The small circles are the experimental points of Martin, Richardson and Hsü[5], and the large ones those of Siegbahn and Johansson[6], obtained with an α-ray recoil source.

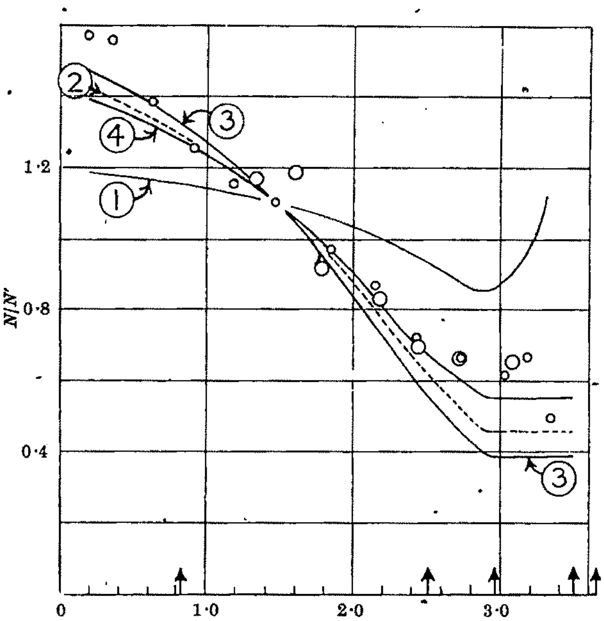

Fig. 2. β-SPECTRUM OF THORIUM $C'' \rightarrow D$. THE ARROWS INDICATE β-END-POINTS ON THE LEVELS IN FIG. 1. CURVE 4 DIFFERS FROM CURVE 2 IN USING INTENSITIES 0·80 AND 0·20 FOR THE M AND P γ-RAYS

Curve (1), with end-point at 1·864 MeV., predicts too many high-energy β-rays. The experiments agree fairly well with curves (2) and (3), except below 0·4 MeV., where a surplus of low-energy β-rays is found. This may be due to a partial β-spectrum exciting one or more levels of Pb^{208} at about 4·55 MeV., as shown by the broken line in Fig. 1. The resulting weak γ-rays of intensity about 0·03 per disintegration have not been identified with certainty, but all the other rays allowed by the selection rules in scheme (*b*) have been found.

The levels should all have the same parity because the observed values of α_K are too large for electric dipole γ-rays. The parity should presumably be even because Pb^{208} is an even-even nucleus with $I = 0$ in the ground-state. It follows that if the β-transition to any one of these levels is allowed, the β-transitions to the others must be either allowed or second or fourth forbidden to avoid a change of parity.

For scheme (*b*) the values of I for the upper levels can then be deduced under the following conditions. (*a*) the G and L γ-rays have $\Delta I = 0$ or ± 1, and the M ray has $\Delta I = \pm 2$; (*b*) the β-transitions to the higher levels are allowed with $\Delta I = 0$ or ± 1 and no parity change; (*c*) the β-transition from ThC″ to the ground-state of Pb^{208} is fourth forbidden and that to the 2·62 MeV. level is second forbidden. These conditions restrict I for the ground-state of ThC″ to be either 5 or 4.

Nucleus	ThC″	Pb^{208}					
Energy of level (MeV.)	0	0	2·62	3·20	3·48	3·71	4·55
Possible set of values of I	5 4 4	0 0 0	2 1 2	4 3 4	4 3 3 or 4	5 4 5	4, 5 or 6 3, 4 or 5 3, 4 or 5

The value 5 leads to a unique set of spin quantum numbers for the five lower levels of Pb^{208}. The value 4 gives the alternative sets shown in the table.

The upper of the two rows with $I = 4$ for ThC″ gives $\Delta I = -1$ for the 2·62 MeV. ray, thus making it pure magnetic dipole radiation. The other choices with $\Delta I = -2$ make it pure electric quadripole radiation.

The term scheme is incomplete because it does not include the weak *Ec* and *Fb* γ-rays.

The Mass of σ-Mesons

The existence of mesons of different masses has been demonstrated by the recent exhaustive papers of Dr. C. F. Powell and his colleagues. We have recently carried out an investigation of the mass of the σ-mesons, that is, those mesons which produce disintegrations in nuclei.

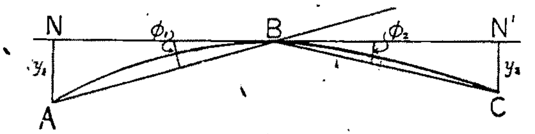

Fig. 1

The method used was that of measuring the Coulomb scattering of the meson in its passage through the emulsion. Hitherto, this method has been utilized only by measuring the angle between the directions of the track at two points along it. It is, however, very difficult to draw tangents to the tracks. Accordingly, we measured the angles ψ between consecutive chords along the track. Let *ABC* in Fig. 1 be the projection of a section of the track in the plane of the emulsion, and the lengths *AB* and *BC*, measured along the track, be each equal to x, say. Draw the tangent *NBN′* at *B*, and join *AB* and *BC*; then the angle between the chords is equal to $(\varphi_1 \pm \varphi_2)$;

$$\therefore (\psi^2)_{av} = (\varphi_1{}^2)_{av} + (\varphi_2{}^2)_{av}.$$

Draw perpendiculars *AN*, *CN′*, of lengths y_1 and y_2 respectively, to *NBN′*; then

$$\varphi_1 = y_1/x \text{ and } \varphi_2 = y_2/x.$$

$$\text{Hence } (\varphi_1{}^2)_{av} = (y_1{}^2)_{av}/x^2 \text{ and } (\varphi_2{}^2)_{av} = (y_2{}^2)_{av}/x^2.$$

If the angle between the tangents at A and B is θ_1, and that between the tangents at B and C is θ_2, it can be shown that

$$\begin{aligned}(y_1{}^2)_{av} &= \tfrac{1}{4}x^2\,(\theta_1{}^2)_{av} \text{ and}\\ (y_2{}^2)_{av} &= \tfrac{1}{4}x^2\,(\theta_2{}^2)_{av}\\ \therefore (\psi^2)_{av} &= \tfrac{1}{4}\,\left((\theta_1{}^2)_{av} + (\theta_2{}^2)_{av}\right),\end{aligned}$$

and $(\theta^2)_{av}$ can be calculated from the formula

$$(\theta^2)_{av} = \frac{4\pi e^4 Z^2 N x}{p^2 v^2} \log\left(\frac{\theta_{max}}{\theta_{min}}\right),$$

where

$$\theta_{min} = \left(\frac{mc}{p}\right)\left(\frac{Z^{1/3}}{181}\right),$$

and θ_{max} is the smallest angle that is recognizable as a single deflexion, Z, N, p and v have their usual meanings.

The advantages of this method are that the chords are easy to draw, and the observations repeatable. The only other method of measuring mass at present is by grain counts along the track, and owing to latent image fading this is not reliable. Also, multiple scattering gives a higher mass resolution for low masses than does grain counting.

We have observed, at the time of writing, some thirty σ-meson tracks, of which fifteen were long enough to investigate. These were traced on the screen of a projection microscope, using a magnification of about 1,500 ×, and divided into twenty μ sections, and the angles between the chords measured. The theoretical values of $(\psi^2)_{av}$ at various distances along the tracks of mesons of mass 200, 360 and 900 electron masses, as well as those for protons, were calculated. It was found that if $(\psi^2)_{av}$ was plotted against range from end of track, the forms of the curves were very similar.

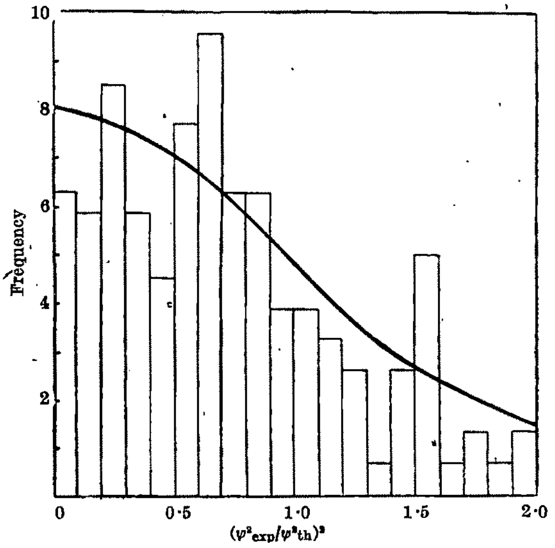

Fig. 2

Therefore, to interpret the results, the values of ψ^2 obtained experimentally at any point were divided by the theoretical value of $(\psi^2)_{av}$ at the same distance from the end of the track, for a meson of mass 300. A histogram (Fig. 2) was plotted of the square root of these quotients against frequency, for all quotients from all tracks. It can be shown that the distribution of multiple scattering angle is Gaussian, and it follows that the distribution of this quotient is also Gaussian, assuming that the mass is always the same. From this it was found that the mass was in the neighbourhood of 300 electron masses. The curve for this mass is shown in Fig. 2. It was also found, however, that the distribution obtained could equally well be explained by assuming mesons of different masses; but the results show that the mesons are not all of mass 200 electron masses. The value of 290 for the mass was also obtained by taking the mean of the values of ψ^2 obtained from the different tracks, at the same distance from the end, and finding the corresponding mass. This was done for all distances, and the mean of the mass values thus obtained taken.

This method would seem to be capable of giving a good estimate of the mean mass of a number of particles; but would be unable to resolve the masses into distinct groups, if such groups occurred. We can, however, say that if any appreciable number of the σ-mesons have mass 200, there must be a corresponding number with mass greater than about 400, and the mean mass is 290 ± 80 electron masses.

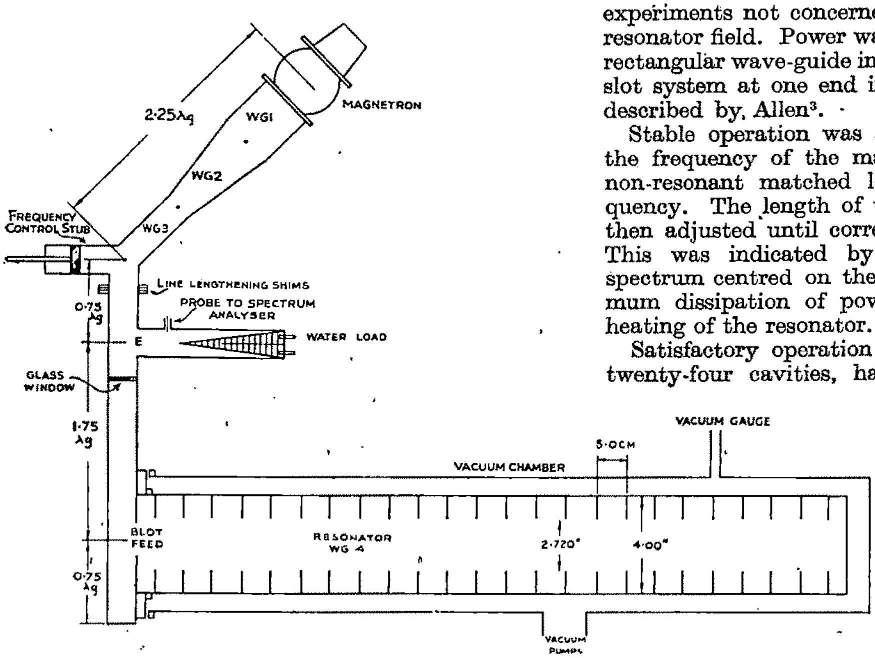
A Method of Feeding Micro-wave Power into a Resonator having a Fine Mode Structure

IN the course of investigations into the design of a micro-wave linear accelerator of the resonant type, to operate at 3,000 mc./s. (cf. Fry[1]), we have succeeded in feeding power into a 24-cavity evacuated resonator 120 cm. long, having a separation in frequency of only 0·2 per cent (that is, 6 Mc./s.) between the required mode of operation and the adjacent mode. The required mode had a phase difference of π between currents in adjacent cavities.

The micro-wave power was generated by an experimental pulsed magnetron, type E 1944, driven at 500 p.p.s. with 2 μsec. pulses by a standard Admiralty type 277 modulator, loaned by the Admiralty Signal Establishment. This modulator had a peak power output of 1·25 MW., and an estimated peak power of 390 kW. was fed into the resonator.



WG	Size	Mode
1	3¼ in. int. diam.	H_{11}
2	Taper	$H_{11} \rightarrow H_{01}$
3	3 in. × 1 in.	H_{01}
4	4 in. int. diam. iris loaded	$E_{0,1,3,4}$

The circuit arrangement is shown in the diagram. The resonator was coupled to the feeding wave-guide in such a way that it was equivalent to a series resonant circuit in parallel with the wave-guide at its point of connexion. The resonant resistance of this was 1/1·2 times the guide characteristic resistance (Z_0). In order to achieve frequency stability in the steady-state condition of oscillation, the effective length of wave-guide between the valve and the resonator was 4·75 guide wave-lengths. The combination of wave-guide and resonator measured at the valve was thus equivalent to a parallel resonant circuit the resistance of which at resonance was 1·2 Z_0. In order to achieve stability during the resonator build-up time, a resistance of the water-load type was placed in series with the wave-guide[2] at such a point that in the steady-state condition it was effectively in series with the resonator, when measured at the valve, and had a resistance of 0·6 Z_0. Consequently, 65 per cent of the generated power was absorbed by the resonator. The magnetron used had a frequency pulling figure of 15 Mc./s., so that in the steady state, with an effective load impedance of 1·8 Z_0 due to the resonator and the stabilizing resistance, its electronic efficiency was reduced from 50 per cent to 45 per cent[3]. The power absorbed by the resonator was thus 60 per cent of the power output of the valve when feeding a matched load. The peak power output when feeding into a non-resonant matched load was 650 kW.; hence the estimated peak power fed into the resonator was 390 kW.

The resonator consisted of a circular wave-guide of 4 in. internal diameter having twenty-four circular irises of diameter 2·720 in. spaced 5 cm. between centres (that is, half the operating wave-length) and closed at both ends by walls spaced 2·5 cm. from the centre of the end irises. The measured Q factor was 8,000, the internal finish being poor; but this factor was considered relatively unimportant for initial experiments not concerned with the strength of the resonator field. Power was fed from the 3 in. × 1 in. rectangular wave-guide into the resonator by a double slot system at one end in a similar manner to that described by Allen[3].

Stable operation was achieved by first adjusting the frequency of the magnetron, operating with a non-resonant matched load, to the resonator frequency. The length of the feeding wave-guide was then adjusted until correct operation was obtained. This was indicated by a very stable frequency spectrum centred on the resonator frequency, minimum dissipation of power in the water load and heating of the resonator.

Satisfactory operation was readily achieved with twenty-four cavities, having an overall length of 120 cm., with a frequency difference between adjacent modes of 0·2 per cent. This frequency difference is theoretically proportional to the inverse square of the number of cavities. From the range of magnetron tuning over which stable operation occurred it is anticipated that a considerably longer resonator, with a correspondingly finer mode structure, can be satisfactorily fed in the required mode by this method.

Fission Products of U^{233}

EXPERIMENTS have been described[1,2] which give data for the fission products of U^{235} produced in thermal neutron irradiation of natural uranium. Recently, a new radioactive series, not present in Nature, has been reported[3,4]. Seaborg has shown that U^{233}, a member of this series, is fissile with neutrons. The following is a summary of the results of a survey of the longer-lived fission products of U^{233}. The data were obtained in conjunction with those previously reported[1], but could not be released for publication at that time.

The relative yields of the fission products are given directly by the equilibrium activities for an infinitely long bombardment at a constant rate. The yield of Ba^{140} from the fission of U^{235} in natural uranium is taken as a reference. Three samples were irradiated simultaneously, one U^{233} and two natural uranium samples. In order to facilitate direct comparison of the fission-product activities in the natural uranium and U^{233} samples, the weights of the respective samples used were such that the number of fissions produced in each were equal.

After irradiation, a chemical separation of each element lying between arsenic and praseodymium was made. Thirty-one active isotopes were found and identified by their half-lives and their β-, γ-ray absorption characteristics. In all cases, identical activities were observed in the natural and U^{233} samples.

The fission yields for U^{233} are presented in the accompanying table together with those for U^{235}. As with U^{235}, a plot of fission yield against mass number shows a double-humped curve indicating a light group and a heavy group.

FISSION YIELDS FOR U^{233} AND U^{235}

Mass number	U^{235}	U^{233}	Active isotope determined	
89	$3 \cdot 2 \times 10^{-2}$	$4 \cdot 1 \times 10^{-2}$	55 d	Sr
90	$4 \cdot 0 \times 10^{-2}$	$3 \cdot 7 \times 10^{-2}$	~30 y	Sr
91	$4 \cdot 0 \times 10^{-2}$	$4 \cdot 1 \times 10^{-2}$	61 d	Y
95	$3 \cdot 2 \times 10^{-2}$	$3 \cdot 9 \times 10^{-2}$	65 d	Zr
103	$8 \cdot 4 \times 10^{-3}$	$2 \cdot 1 \times 10^{-3}$	37 d	Ru
106	$1 \cdot 5 \times 10^{-3}$	$6 \cdot 4 \times 10^{-4}$	290 d	Ru
111	$1 \cdot 6 \times 10^{-4}$	$1 \cdot 5 \times 10^{-4}$	7·5 d	Ag
(123)	$6 \cdot 4 \times 10^{-6}$	$1 \cdot 9 \times 10^{-5}$	~18 d	Sn
(123)	$8 \cdot 5 \times 10^{-6}$	$2 \cdot 5 \times 10^{-5}$	136 d	Sn
127	$1 \cdot 5 \times 10^{-4}$	$6 \cdot 7 \times 10^{-4}$	90 d	Te
125	$8 \cdot 9 \times 10^{-5}$	$6 \cdot 0 \times 10^{-4}$	~10 y	Sb
129	$9 \cdot 0 \times 10^{-4}$	$2 \cdot 2 \times 10^{-3}$	32 d	Te
131	$1 \cdot 5 \times 10^{-2}$	$2 \cdot 4 \times 10^{-2}$	8·1 d	I
132	$4 \cdot 9 \times 10^{-2}$	$4 \cdot 9 \times 10^{-2}$	2·3 h	I
137	$1 \cdot 8 \times 10^{-2}$	$1 \cdot 8 \times 10^{-2}$	33 y	Cs
(136)	$\sim 10^{-4}$	$\sim 10^{-4}$	~20 d	Cs
140	$5 \cdot 6 \times 10^{-2}$	$6 \cdot 7 \times 10^{-2}$	40 h	La
144	$2 \cdot 9 \times 10^{-2}$	$2 \cdot 2 \times 10^{-2}$	290 d	Ce
147	$\sim 6 \times 10^{-3}$	$\sim 6 \times 10^{-3}$	~4 y	61

In U^{233} fission the groups have a similar shape to those for U^{235} but are one unit lower on the mass scale. The maxima of the fission-yield curves are approximately the same in all cases, being approximately 6×10^{-2}.

A detailed account of the investigation is to be published.

Fluorescence of Highly Insulating Dielectrics Produced by X- and γ-Radiations

IN the course of experiments designed to study photographically the secondary electron emission from various light-atom materials when they are irradiated with high-voltage X-rays, we have found that under certain radiation conditions some highly insulating dielectrics fluoresce when so irradiated, visible and possibly ultra-violet light being emitted. Polystyrene in the commercial form known as 'Distrene' shows the phenomenon quite markedly.

In our first experiments, using X-rays generated at 200 kVp. (half-value layer, 2 mm. copper), the photographic blackening due to secondary electronic emission[1,2,3] was being examined for a range of light-atom materials which included amber, 'Perspex', paraffin wax, 'Alkathene' and 'Distrene', and for such elements as carbon, sulphur, aluminium, copper, silver, tin, gold and lead. The density of blackening obtained for the light-atom materials was much as one would theoretically expect with the exception of 'Distrene'; for this material the density was almost as great as that for copper. Various samples were used with always the same result. It was suggested by Dr. F. W. Spiers that the extra unexpected density might be due to fluorescent radiation, and this is so. A single layer of black paper was found to absorb the radiation and reduce the density of blackening to expected values; the transmission through various thicknesses of glass suggested that some of the radiation might be ultra-violet as well as visible.

The same light-atom materials were examined visually in the dark while they were irradiated with X-rays. No definite fluorescence could be seen from amber, only a faint suggestion was seen from paraffin wax, 'Perspex', and 'Alkathene'; but quite a strong diffuse whitish fluorescence was observed from 'Distrene'. Similar observations were made using X-rays generated at 110 kVp. and 60 kVp. No apparent afterglow was seen; as the X-ray beam was switched off so the fluorescence disappeared.

Similar experiments were made in the dark using the gamma-ray beam from a 2-gm. radium mass unit[4]. In this case a feeble fluorescence of a similar colour was seen from amber and 'Perspex' and quite a strong fluorescence from paraffin wax, 'Alkathene' and 'Distrene'. This fluorescence was also detectable photographically for paraffin wax as well as 'Distrene', but nothing could be detected from 'Perspex' by this means. Again no apparent afterglow could be seen even when the materials were left in the gamma-ray beam for a whole week-end.

Mallet[5] referred to the fluorescence under γ-irradiation of some fluids, including water, grease, oil, albumin and blood serum, and Newcomer[6], in a paper dealing with the fluorescence under X-irradiation of some five hundred compounds, mostly organic, refers to the fluorescence of his paraffined paper cups as being barely within the limits of visibility.

The fluorescence observed in 'Distrene' may be related to the observation by Farmer[7] that, after receiving a considerable dose of X-rays, the insulating properties of 'Distrene' are impaired. Slight traces of impurities are known to be sometimes responsible for fluorescence in many substances, and it is likely that something of this nature may be the responsible agent in this case. If this is so, their removal might conceivably eliminate the phenomenon and improve the insulating properties of 'Distrene' under X-irradiation.

A use of this property of 'Distrene' which suggests itself is as an intensifying screen for certain purposes. If photographic response to X-rays could be made independent of wave-length, such response could be used for measuring X-ray dose and dose distribution. Independence of wave-length might be more nearly realized by the use of suitable intensifying screens; but a difficulty, particularly for phantom measurements, is absorption in the screens. Sheet 'Distrene' would act as a light-atom intensifying screen which would possibly eliminate absorption difficulties and might lead to the required wave-length independence.

Transition from Glow to Arc Discharge

I have suggested[1] a mechanism to account for the occurrence of long electrical discharges in electric fields which are only of the order of one per cent of those generally believed[2,3] necessary to cause sparkover. In the case of the leader stroke of the lightning discharge, the integrated lateral corona currents from the channel ultimately reach values of the order of thousands of amperes[4], so that the characteristics of the channel must be those of the electric arc, though the discharge must start as a brush or glow discharge. This consideration led me to suggest that the steps in the initial leader stroke represent the transition of successive lengths of the channel from glow to arc conditions, and that a self-propagating discharge is initiated by this transition.

It has been contended[5], in criticism of this view, that the phenomenon of glow to arc transition is entirely governed by the conditions at the cathode, and not at all by those in the discharge column. Experiments in these laboratories have, however, shown that a clearly discernible transition, of the nature usually described as that of glow to arc, occurs in a discharge, which is certainly independent of conditions at the cathode.

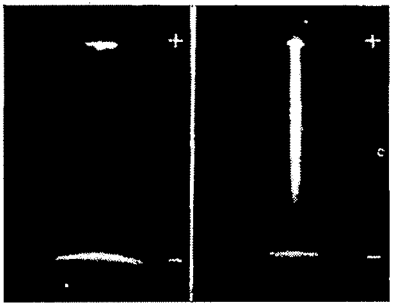

Fig. 1. Stroboscopic photographs of 1 cm. a.c. discharge in hydrogen. (*a*) 0·9 amp.; (*b*) 1·6 amp. Actual exposure times, 2 sec. and 1 sec. respectively

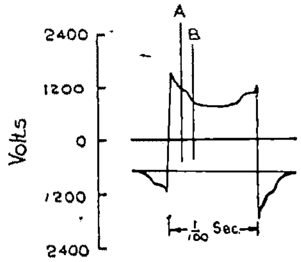

Fig. 2. Oscillogram of voltage across discharge. Photographs of Fig. 1 taken at *A* and *B*

Fig. 1 shows two stroboscopic photographs taken before and after this transition has occurred in an alternating current discharge between water-cooled copper electrodes 1 cm. apart in hydrogen at atmospheric pressure, the peak current being 2 amp. At about 35 electrical degrees after current zero, that is, at a current of about 1·2 amp., the discharge column begins in the region of the anode to change from a diffuse glow to the narrow, bright, crimson column of the hydrogen arc. By the time the current reaches 1·5 amp. this condition has spread along the column to the vicinity of the cathode, which last, however, remains covered by the characteristic wide-spread glow of the glow discharge throughout. The cathode fall of potential likewise remains constant throughout at about 350 volts, whereas the potential gradient along the column falls from about 650 V./cm. in the glow phase to 350 V./cm. in the arc phase. Thus two interesting discharge conditions would appear to have been obtained, namely, a discharge with the column in the arc state while glow conditions persist at the cathode, and one in which the transition occurs in the discharge column itself.

The transition from glow to arc is dependent on the gas pressure as well as on the current in the discharge. In particular it has been observed by several investigators[6] that it does not occur at all below a gas pressure of the order of one hundredth of an atmosphere. This is just about the pressure at the surface of the solar photosphere, and, on a theory I have advanced[7], the latter surface is the result of the occurrence of this transition. Conversely, this agreement supports the view that the transition is a phenomenon primarily of the column and not of the electrode surface.

A fuller account of this work and its application to the spark discharge will appear in due course. I am indebted to my colleague, L. A. King, for much of the experimental work.

Photography on Selenium

IT was observed many years ago that the crystallization of amorphous selenium is promoted and accelerated by illumination[1,2]. I rediscovered this in the summer of 1941 and succeeded in producing true photographic images by means of this effect, using the initial product of selenium manufacture, namely, aluminium or steel disks covered with a film of selenium, as photosensitive plates. To do this, the mirror-like surface of the selenium must be polished with a soft material, such as tissue paper. The disk is then placed on a metal plate, preheated at 90–95° C., and an image, preferably a diapositive, projected on the surface of the selenium. During exposure, 'self-development' takes place and in 1–2 minutes a somewhat faint but in other respects perfect image will appear. The photographic process is then complete and the disk can be removed from the hot plate.

The image is produced by progressive crystallization of the amorphous selenium. It causes the selenium surface to lose its lustre, to become velvet-like in texture, diffusing the light and changing its colour from black to grey, gradually and in proportion to the intensity of the incident light, that is, with the brightness of the different parts of the projected image. In consequence of this the copy of a positive image will be also a positive. Over-exposure rapidly deteriorates the image and turns it finally into a roughly crystalline uniform surface of grey colour.

The 'trick' of polishing (that is, covering the surface with very fine scratches) is of decisive importance: it facilitates the crystallization and makes this capricious process uniform and regular. Pure selenium crystallizes slowly: the selenium we used was mixed with 0·07 per cent iodine; increasing the iodine content would probably be advantageous.

Another method of 'selenography'—also in connexion with rectifier manufacture—is based upon my observation that the imperfectly reflecting black surface (at 100–120° C.) of hot-pressed, crystalline selenium changes to a light grey-coloured one; this takes place in the usual second heat treatment at about 210° C., and is also promoted by illumination.

Collision Broadening of the Ammonia Inversion Spectrum at High Pressures

THE collision broadening of the inversion spectrum of ammonia has been studied by Bleaney and Penrose[1] at pressures up to 600 mm. mercury. The line-widths, measured at a pressure of 0·5 mm. mercury, give values for the collision diameters (for self-broadening) varying between 8·7 A. and 14·2 A., with a mean value (weighted according to the line strengths) of 13·2 A. Between 0·5 mm. and 100 mm. pressure, the shape of the absorption curve agrees closely with that calculated from the intensity and position of the individual lines, assuming that their widths vary linearly with the pressure. At 600 mm. pressure, however, the absorption maximum has shifted to less than 0·6 cm.$^{-1}$, and the curve shape is no longer consistent with that calculated from the structure factor of Van Vleck and Weisskopf[2], and Fröhlich[3], using the extrapolated line-widths.

These measurements have been extended to delineate the absorption curve in ammonia gas over the frequency-range 0·1–1·2 cm.$^{-1}$ at pressures up to six atmospheres. The absorption was determined from the damping of a resonator caused by the admission of the gas, by a technique similar to that of Bleaney and Penrose[4]. A cavity resonant in the H_1 mode was used, however, in order to avoid errors due to the tails of other resonances, which can occur in an H_0 cavity when filling it with a fluid of appreciable dielectric constant (see Bleaney, Loubser and Penrose[5]).

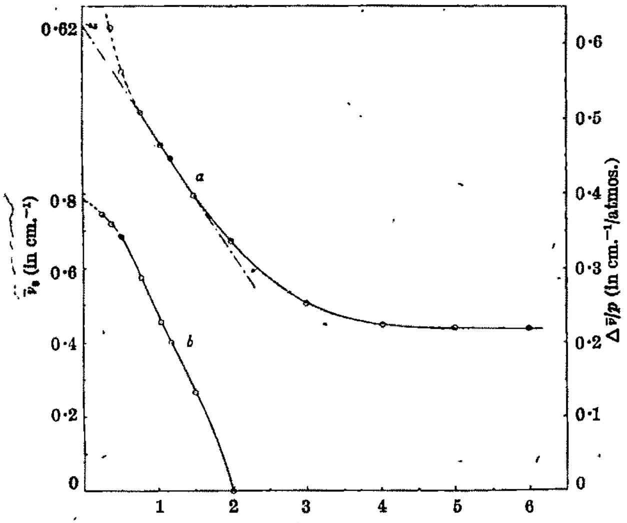
At high pressures the widths of the individual lines of the ammonia spectrum become large compared with their separation, and it should be possible to represent the observed line by the formula

$$\frac{\alpha}{\bar{\nu}^2} = \frac{4\pi^2}{3kT} \sum_{J,K} N_{J,K} \, | \mu_{J,K} |^2 \left\{ \frac{\Delta\bar{\nu}}{\Delta\bar{\nu}^2 + (\bar{\nu}_0 - \bar{\nu})^2} + \frac{\Delta\nu}{\Delta\bar{\nu}^2 + (\bar{\nu}_0 + \bar{\nu})^2} \right\}. \quad (1)$$

The whole resonance curve is thus treated as if due to a single line of resonant frequency $\bar{\nu}_0$, with a line-breadth constant $\Delta\bar{\nu}$, and an intensity corresponding to the sum of the intensities of the individual lines. It is found that above 10 cm. pressure, the experimental absorption curves can be adequately represented by this formula using empirical values of $\bar{\nu}_0$ and $\Delta\bar{\nu}$ to give the best fit at each pressure. The variation of these values is shown in the accompanying graph, where $\bar{\nu}_0$ and $(\Delta\bar{\nu}/p)$ are shown as functions of the pressure (p in atmospheres). At zero pressure $\bar{\nu}_0 = 0{\cdot}78$ cm.$^{-1}$ corresponds to the centre of gravity of the absorption band, and $\Delta\bar{\nu}/p = 0{\cdot}62$ cm.$^{-1}$ per atmosphere corresponds to the average collision diameter of 13·2 A. As the pressure increases, the resonant frequency $\bar{\nu}_0$ shifts steadily downwards, becoming substantially zero at 2 atmospheres and above. At the same time, the value of $(\Delta\bar{\nu}/p)$ decreases, showing that the collision frequency no longer increases linearly with the pressure. (Here the dotted curve at low pressures has no meaning, since the rotational fine structure of the inversion band gives an artificial width not due to collision broadening.)

The initial portion of the $(\Delta\bar{\nu}/p)-p$ curve (up to about 2 atmos.) can be represented by the formula

$$\Delta\bar{\nu} = 0{\cdot}62\, p\, (1 - bp) \text{ cm.}^{-1} \ (p \text{ in atmospheres}), \quad (2)$$



CURVE *a*, $\Delta\bar{\nu}/p$ AGAINST *p*. CURVE *b*, $\bar{\nu}_0$ AGAINST *p*

where the coefficient *b* has the value of 0·25 atmos.$^{-1}$. The fall in $(\Delta\bar{\nu}/p)$ may be ascribed to the effect of double collisions. Since the collision diameter is considerably greater than the kinetic theory diameter, an absorbing molecule *A* will have a colliding molecule *B* within its sphere of influence for a fraction $\frac{4\pi}{3}\sigma^3 N$ (where *N* is number of molecules per c.c.) of the total time. If another molecule collides with it during this time, the collision is not effective in contributing to the line-width, since the absorption of radiation was already interrupted. The line-width therefore rises less rapidly than the pressure by the factor $(1 - \frac{4\pi}{3}\sigma^3 N) = (1 - 0{\cdot}23p)$, in close agreement with the experimental formula (2). As the pressure rises still further, the probability of multiple encounters increases, until at about 4 atmospheres the molecule would be spending practically all its life in 'collision'.

The fall in the resonant frequency to zero at about 2 atmospheres represents the destruction of the inversion of the ammonia molecule, either due to the fact that the mean time between collisions $(1/2\pi c\Delta\bar{\nu})$ is then only a fraction of the natural period of the inversion, or to the enormous fluctuating electric fields of the surrounding dipoles. Van Vleck and Weisskopf point out that the formula (1) for the shape of the line should still be valid when $\Delta\bar{\nu} \approx \bar{\nu}_0$. The destruction of the inversion must therefore be ascribed to the electrical interaction, which for two ammonia dipoles with a separation of 27 A. (the mean distance between the molecules at 2 atmos. pressure) corresponds to an energy of 0·5 cm.$^{-1}$. Since each molecule has a number of nearest neighbours, the mean energy will be considerably greater than this, and it seems reasonable that the random electric field can destroy the inversion doublet in the energy levels, and so substitute a non-resonant inversion similar to that observed in heavier molecules. The facts that the line-breadth constant becomes again proportional to the pressure (but with a smaller collision diameter of 7·6 A.) and the total intensity is the same as for the resonant inversion are in agreement with this hypothesis. If, on the other hand, a true Debye absorption, similar to that observed in polar liquids, had set in, the intensity would be greater by a factor of about 2·5, and one might expect the line-breadth constant to be independent of the pressure, like the viscosity of a gas.

To determine whether the destruction of the resonant inversion is indeed due to the electrical interaction and not simply to the high collision frequency, measurements are being undertaken on mixtures of ammonia with non-polar gases at high pressures. In this way it should be possible to increase the value of the line-breadth constant without a corresponding increase in the fluctuating electric field in which the ammonia molecule moves.

Coefficients of Viscosity and Thermal Conduction in Dense Gases and Liquids

THE coefficients of viscosity and thermal conduction in dense gases and liquids have never been deduced from the molecular point of view owing to the difficulties arising from the statistical treatment of the dense and disordered state. Since a general kinetic theory of liquids has been successfully formulated by Born and Green[1], it has been found possible to deduce these coefficients apart from constant factors. Each of them is seen to consist of two parts, one due to the thermal motion of the molecules and the other to molecular attraction. In every case the radial distribution function plays an important part. For dilute gases, the first part predominates, while for liquids the second part is by far the more important. The different behaviour of liquids and gases in respect to viscosity and thermal conduction can thus be accounted for.

The general expressions for the coefficients of viscosity (μ) and thermal conduction (λ) are, in first approximation,

$$\mu = \frac{(mkT)^{1/2}}{a}\left(1 + \frac{L}{nkT}\right)\left(C_k + C_p\,\frac{L}{nkT}\right);$$

$$\lambda = \frac{k}{a}\left(\frac{kT}{m}\right)^{1/2}\left(1 + \frac{L}{nkT}\right)\left[A_k + A_p\,\frac{L}{nkT}\left(1 - \gamma\,\frac{T\frac{\partial p}{\partial T}}{n\frac{\partial p}{\partial n}}\right)\right];$$

where *a* is the effective collision diameter which for rigid spheres would be constant and for other force laws varies slowly with temperature, while

$$L = -\frac{2\pi}{3}\int_0^\infty n_2(r)\,\varphi'(r)\,r^3\,dr\,;$$

$$p = nkT + L.$$

φ(*r*) is the mutual potential energy between a pair of molecules regarded as a function of the distance *r* between their mean centres only, *m* the molecular mass, *n* the number density, *k* is Boltzmann's constant, T the absolute temperature, $n_2(r)/n$ the radial distribution function and C_k, C_p, A_k, A_p, γ are numerical constants.

The first part of μ and λ can be shown to reduce to the corresponding formulæ in gas theory[2] for the case of rigid spheres, and the relation $\lambda = \mu C_v$, where $C_v = 3k/2m$, can be seen to hold for any model.

It should be possible to fix the constant coefficients if sufficient knowledge of the radial distribution function and its rate of change with density and temperature could be obtained. Theoretical investigations of this problem are now in progress in this Department.

I wish to express my thanks to Prof. Max Born, who suggested this problem to me, and to Dr. H. S. Green for his advice.

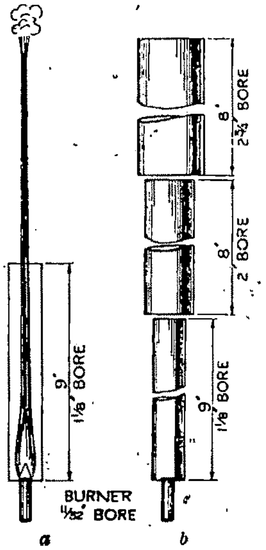
A Bunsen Flame as a Column of Luminous Gas

The long duration of the luminosity (afterglow) of flame gases after the explosion of a well-mixed inflammable gaseous mixture contained in a large closed vessel, in which cooling takes place slowly[1], suggests that were it possible to secure steady streamlined flow of the flame gases rising from a very large open flame, thus eliminating cooling due to turbulence, they would appear as a column of luminous gas many feet in height. Experimenting recently, we have been a little surprised to find how far we may go in this direction with a small Bunsen flame resulting from the combustion of fully aerated coal-gas. It is easily possible to obtain a column of luminous gas which, viewed in a dark room, extends to a height of 2 ft., whereas with the ordinary Bunsen flame luminosity ceases at a height of only 7 or 8 in.

All that is necessary is to hold an open-ended tube around the flame, as shown in Fig. *a*. It is important that a tube of the right diameter and length in relation to the burner diameter should be selected. The dimensions of the tube used in our experiments are given in the figure.



An even greater height of luminous gas column—approaching 3 ft.—may be attained by the use of a series of open-ended tubes of increasing diameter placed one above the other, as shown in Fig. *b*.

It would appear that the flame gases become embedded in a column of expanding air rising through the tube, and the turbulent mixing with cold air, which always takes place near the tip of an ordinary flame (see *Schlieren* photographs[2]), is thus inhibited. The provision of additional tubes above the first appears to assist in maintaining the streamline flow.

The first six inches or so of the flame gases are yellow in colour. They then turn to red and quickly afterwards to blue, which persists through the whole length of the column. The yellow coloration indicates continued combustion above the inner cone due to stratification of the gas mixture in the flame resulting from imperfect mixing of the coal-gas and air during their passage up the burner tube. When a perfectly mixed coal-gas and air mixture (with excess air) contained in a tank is supplied to the burner (with the air port closed) there is no yellow coloration—the flame gases attain their reddish colour immediately above the inner cone and this turns quickly to the characteristic blue afterglow which persists as before.

We have obtained a similarly extended afterglow when burning pure carbon monoxide in the Bunsen burner.

We would again like to suggest that it is difficult to account for the long duration of the afterglow unless the presence in the flame gases of metastable molecules formed during combustion is assumed[1]. The excited molecules responsible for the light emission may result from the collisions of these molecules.

Equations of Piezo-electricity

Prof. W. G. Cady's exposition of the basic equations of piezo-electricity in his recent book "Piezoelectricity" contains errors which should be brought to the attention of students and workers in this field.

On p. 44, the first thermodynamic potential is introduced in equation (1), but is incorrectly expressed as a quadratic form in terms of elastic strains and electric field intensities within the piezo-electric material (we are considering only isothermal effects here). This potential is also called Green's strain-energy function, and is identical with the Lagrange function for a statical conservative system. It is well known that, for a linear conservative system, this function can be written either as a quadratic form in the generalized co-ordinates, in which case it is sometimes called the 'first thermodynamic potential', or as a quadratic form in the generalized forces, when it is called the 'second thermodynamic potential'. For an electromechanical system, suitable generalized co-ordinates are elastic strain and electric displacement, and the corresponding generalized forces are elastic stress and electric field intensity. By using elastic strain and electric field intensity in equation (1), however, Prof. Cady mixes generalized co-ordinates and forces in the Lagrange function, which results in erroneous piezo-electric equations. The second thermodynamic potential is introduced in equation (2) on p. 44, and is correctly written as a quadratic form in elastic stress and electric field intensity. Equations based on (1) will be physically inconsistent with equations based on (2).

Theoretical conclusions drawn from the incorrect equation (1) by the usual Lagrange formalism permeate the whole of Chapter 8 on the principles of piezo-electricity. The correct equation (2) is also used as a basis for many of the equations in this same chapter, and the reader is therefore obliged to examine closely the origin of the formulæ he uses. The formulæ affected are the basically important linear equations which give the elastic stresses and electric field intensities as functions of the elastic strains and electric displacements.

The basic formulæ are used in subsequent chapters on the piezo-electric properties of certain crystals, on alternative formulations of piezo-electricity theory, and on secondary piezo-electric effects. On page 252 of the chapter on alternative formulations of theory, incidentally, the author introduces equations (243) and (243*a*), which are similar to (1) and (2), and in which again generalized forces and co-ordinates are incorrectly mixed in the Lagrange function.

Prof. Cady's book fills the need for a comprehensive summary of the recent experimental researches; the mathematical portions, however, require revision.

The Melanin Problem: a Synthesis of 5:6-Dihydroxyindole

WE have recently submitted to the Chemical Society a paper describing, *inter alia*, a new synthesis of 5-hydroxyindole by reduction with iron powder and acetic acid of 2:β-dinitro-5-acetoxystyrene and deacetylation of the resulting 5-acetoxyindole. As a part of a comprehensive investigation of the chemistry of the natural melanins, we have now successfully extended the method to the synthesis of 5:6-diacetoxyindole (compact hemispherical clusters, m.p. 135–136°; found: C, 61·5; H, 4·9; N, 6·3: $C_{12}H_{11}O_4N$ requires C, 61·8; H, 4·7; N, 6·0 per cent), and of 5:6-dihydroxyindole (colourless needles, m.p. 140°; found: C, 64·7; H, 4·85; N, 9·4: $C_8H_7O_2N$ requires C, 64·4; H, 4·7; N, 9·4 per cent). The latter compound was postulated by Raper[1] as an unstable intermediate in the enzyme-catalysed oxidation of tyrosine to melanin, and has been known hitherto only in solution or in the form of its derivatives.

Treatment of the alkaline deacetylation mixture with dimethyl sulphate, without isolation of the hydroxyindole, yielded the dimethyl-ether (m.p. 155°, in agreement with Raper's 5:6-dimethoxyindole, m.p. 154–155°; found: C, 67·6; H, 6·0; calculated for $C_{10}H_{11}O_2N$ C, 67·8; H, 6·2 per cent).

Crystalline 5:6-dihydroxyindole is surprisingly stable, but in slightly alkaline solution very rapid oxidation occurs with formation of melanin-like products. A study of the oxidation of this dihydroxyindole, its alkyl substitution products and related compounds, which have been synthesized, is in active progress.

The Carotenoids of the Locust Integument

As part of a research programme into the biochemistry of locust pigmentation, the carotenoids of the integument of *Locusta migratoria migratoroides* R. and F. and *Schistocerca gregaria*, Forsk. have been investigated. There is apparently no reference in the literature to the pigment of *Locusta*, and only two rather tenuous and contradictory reports have appeared concerning that of *Schistocerca*[1,2]. Lederer[1] quotes unpublished work with Volkonsky indicating that the rose pigment of young *Schistocerca* is not a carotenoid but that the yellow pigment of the mature insect is; Chauvin[2] reported an unidentified rose-coloured carotenoid in immature, and a mixture of α- and β-carotene in mature, insects.

The insects used in the present investigation were bred in captivity and fed solely on grass. The pigment in the hypodermis of both *Locusta* and *Schistocerca* is the same and undoubtedly astaxanthin[3]. Its identity has been established by comparing its properties with an authentic specimen of astaxanthin isolated from lobster carapaces. Both compounds gave identical absorption spectra in three solvents, namely, petroleum-ether, b.p. 40–60°, pyridine and carbon disulphide; a mixture of the two pigments could not be separated chromatographically. Further, the locust astaxanthin reacted with potassium butoxide *in vacuo* to form a purplish-blue enol salt, and was converted into astacene by alkali in the presence of oxygen. The astacene formed was indistinguishable from lobster astacene.

Partition experiments indicate that astaxanthin occurs in the free form and is not esterified. It occurs in both the solitary and gregarious phases, and at all stages of development up to sexual maturity; up to this stage it is the predominant carotenoid present. It must be formed by the insect, for it does not occur in the diet.

At sexual maturity β-carotene, always present in the fatty tissues of the insects, begins to accumulate in the hypodermis and the astaxanthin to disappear. This observation confirms and explains the work of Chauvin and of Lederer on mature insects. It is, however, difficult to accept unreservedly Lederer's contention that the yellow pigmentation of mature *Schistocerca* is entirely due to carotenoids; so-called acridioxanthin[4] undoubtedly plays some part. This disappearance of astaxanthin, with replacement by β-carotene, at sexual maturity has no obvious explanation at present; but it is another addition to the growing mass of observations which suggests a relationship between carotenoid metabolism and sexual function. It is interesting to note that astaxanthin is also present in the eyes of locusts in both mature and immature insects.

The pigmentation of the gonads and fatty tissues of both species is due almost completely to β-carotene; there may be a little α-carotene present but no traces of xanthophylls could be detected; the amount of β-carotene which accumulates, especially in older insects, is considerable. Previous workers[1] have claimed that this pigmentation is due to a mixture of carotenes and xanthophylls but, more recently, Grayson[5], and Grayson and Tauber[6] have reported findings on another acridid (*Melanoplus bivattus* Say.) which are in substantial agreement with ours, although they report the presence of traces of xanthophylls.

The demonstration of astaxanthin in locusts is particularly interesting because, apart from its detection in the retina and eye colourings of birds[7,8], this is the first time it has been reported in land animals. This is perhaps less surprising when one considers that locusts are quite closely related to the Crustacea, the typical carotenoid of which is astaxanthin.

We are grateful to the Anti-Locust Research Centre for supplying material and for a grant towards expenses.

Isolation in Chick Embryos of a Filtrable Agent possibly related etiologically to Lumpy Skin Disease of Cattle

The widespread occurrence of lumpy skin disease[1] in dairy herds of the Cape Peninsula offered suitable material for investigations on the etiology of this disease.

Skin nodules or lymph gland excised under local anæsthesia from cases in the early stages of the disease as well as tissues obtained at post mortem were made available to us. Emulsions of these tissues, treated with antibiotics or freed of bacteria by filtration through 'Gradocol' membranes[2], were used for the inoculation of laboratory animals and chick embryos.

Inoculation of laboratory animals by the usual routes has so far proved unsuccessful.

One series of experiments using chick embryos has, however, resulted in the isolation of a virus. The starting material was obtained from a calf which died at a stage of the disease when active skin and lymph gland lesions were still present. An emulsion was made in broth of a lymph gland and a skin nodule. After light centrifugation and removal of the supernatant, penicillin (100 μ per ml.) and streptomycin (50 γ per ml.) were added, and the emulsion then filtered through a 'Gradocol' membrane with an average pore diameter of 600 mμ. The filtrate was used for the inoculation of six nine-day-old chick embryos by the combined amniotic and chorio-allantoic routes.

The eggs were returned to an incubator and maintained at 35–36° C. Four of the embryos were dead on or before the sixth day after inoculation. One of the survivors, opened on the sixth day, showed a marked gelatinous œdema of the chorio-allantois and numerous hæmorrhages into the shafts of the feather follicles.

Serial passages of embryo and chorio-allantois have been maintained since then for more than a year. Nine-day embryos are usually employed, and lesions developed by them are constant. On the fourth day after inoculation, the embryos present a characteristic shrivelled appearance—tightly rolled up in a dry, thickened amniotic membrane. Feather development is usually absent, or only irregularly swollen cystic or hæmorrhagic feather follicles are present. The chorio-allantoic membrane almost invariably shov gross gelatinous œdema. That the agent responsib for these lesions is a virus is suggested by: (*a*) th presence of numerous inclusion bodies in histologic sections of affected embryos; and (*b*) the develo ment of lesions following the inoculation of filtrat through 'Gradocol' membranes with A.P.D. of 52 m or more; filtrates through 21 mμ membranes hav regularly failed to elicit the characteristic lesions.

Successful neutralization experiments have bee carried out in eggs, with immune sera from adu fowls that had received repeated injections of th virus cultivated in chick embryos, as well as se from convalescent bovines. Results of neutralizatio tests have, however, not always been conclusiv because positive results have been obtained with th serum of occasional apparently normal bovines. Th possibility that these apparently normal animals ha suffered subclinical infections could not, however, b excluded. Also, one serum from a bovine convalescen after a typical attack of lumpy skin disease co tained no demonstrable neutralizing antibody.

A small number of normal bovines obtained fro areas where the disease was not endemic have bee tested for their susceptibility to the virus cultivate in eggs. None of these has developed lumpy sk disease. The experimental transmission of the disea in its natural host has, however, proved uncerta even when presumably infective inocula obtaine from other bovines have been used. Furthermore, would not be surprising in the light of experien with other animal viruses if serial transfer in eggs ha resulted in a loss of virulence for the original host.

Although the identity of the virus has not yet bee definitely established, it is felt that the successf neutralization by the majority of lumpy skin co valescent sera tested indicates the possible etiologic relationship of this virus to lumpy skin disease.

Full details of the experiments will be publishe elsewhere.

Effect of Calcium Ions on the Charge of Myosin

During a preliminary investigation of the electr phoretic behaviour of the crystalline myosin prepare according to Szent-Györgyi[1] we found, in a Tiseli electrophoresis cell, that myosin was negativel charged when dissolved in potassium chloride pH 7·1.

Based upon these data, Szent-Györgyi suggeste that myosin dissolved in an excess of calcium chlori at the same pH ought to be positively charged. O present experiments confirm this suggestion.

Some data of our preliminary work are summarize in the accompanying table.

Once-crystallized myosin dissolved in the given buffer. Concentration of myosin 0·3 per cent

	*p*H	Mobilit
0·28 *M* KCl	7·1	−2·5
0·12 *M* K-veronale-acetate-HCl buffer of Michaelis	5·6	+1·6
0·22 *M* $CaCl_2$	7·5	+1·2
0·04 *M* K-veronale-acetate-HCl buffer of Michaelis	8·7	+1·2

The isoelectric point of myosin is about pH 5·4. The figures show that the isoelectric point of our calcium myosinate is at a pH greater than 8·7. Myosin is precipitated under our experimental conditions in the presence of potassium chloride in the pH-range 5–6, but in the presence of calcium chloride the myosin is completely soluble in this range.

The difference between the isoelectric points of potassium myosinate and calcium myosinate is undoubtedly unusually large, and it seems to us that this example of potassium – calcium antagonism is of physiological importance.

The investigations are being continued and a detailed description will appear elsewhere. We wish to express our thanks to Prof. Arne Tiselius for his interest in the work. The investigation is financially supported by Svenska Naturvetenskapliga Forskningsrådet.

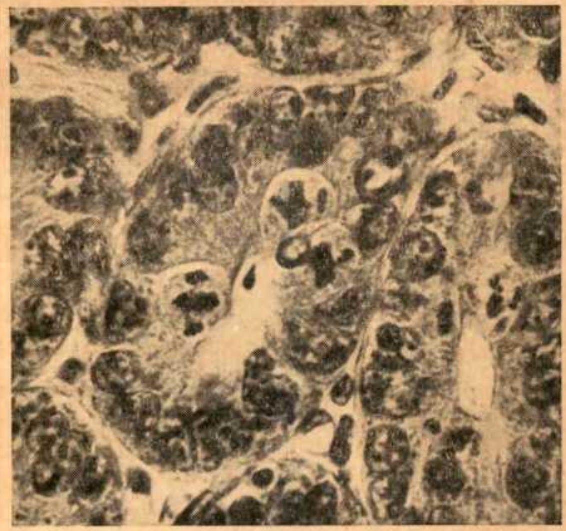
Early Effects of Hydroquinone on Mitosis

ONE of us recently directed attention[1] to the 'radiomimetic' action of hydroquinone. In the intestine of the mouse, extensive nuclear destruction, occurring before the onset of prophase in the cells of the germinative region, was observed four hours after an injection of 0·125 mgm./gm. The interest taken in this type of mitotic poisoning has been increased by the description by Mitchell and Simon-Reuss[2] of the synergic effects of X-rays and a vitamin K substitute (diphosphoric ester of methylnaphthoquinone) on mitosis in normal and cancerous tissues. Naphthoquinone is known to be a mitotic poison[3]. A further investigation of the cytological disturbances following the injection of various quinone and phenolic compounds has led to the observation in the small intestine of the mouse of a new type of abnormal mitosis.

During the first two hours after hydroquinone injection, preceding the 'radiomimetic' (pycnotic) effect, there is a progressive accumulation of arrested metaphases. After intraperitoneal or subcutaneous doses of 0·15 or 0·175 mgm./gm., the percentage of metaphases may rise as high as 92 per cent, while normal ana- and telo-phases nearly completely disappear. Some of the metaphases show an irregular distribution of the chromosomes, which are short and thick and may clump together in the middle of the cell. Most of the divisions, however, assume a very peculiar appearance (see accompanying reproduction). On each side of the metaphase plate, little groups of chromosomes migrate towards the poles. These chromosomes are usually the smallest ones, and their movements are caused by the presence of an [illegible] ently well-developed spindle, easily demo[illegible] after Carnoy fixation.

Various hypotheses may be used to ex[illegible] origin of these abnormal mitoses, whic[illegible] curious resemblance to those normally fo[illegible]



GERMINATIVE REGION OF THE SMALL INTESTINE OF MOUSE

Carnoy fixation, iron-hæmatoxylin staining. In one crypt, three mitoses are arrested. The greatest part of their chromosomes lies in the equatorial region, while small groups of chromosomes have already reached the poles (two hours after 0·135 mgm./gm. hydroquinone)

30 min. and one hour after the injection, when the chromosomes are still clearly defined, only a few of them have migrated to the poles, and there is no evidence that these have yet been broken.

(2) Signs of chromosome 'stickiness' are particularly apparent from one hour onwards after the injection. The central mass of chromosomes clumps more and more together, and bridges may be observed between it and the polar chromosomes. But this is only a secondary change, the abnormal migration taking place when the limits of the equatorial chromosomes are still visible.

(3) Through a defect of the spindle, chromosomes could be 'lost' before the anaphasic migration: v. Moellendorff, in tissue cultures treated with various mitotic poisons, has described such 'detached' chromosomes[5]. However, after hydroquinone poisoning, the spindle appears to be normal, its fibres are quite conspicuous, and it is difficult to understand how so many chromosomes at a time could break loose from the spindle.

(4) An intrinsic cause of the abnormal chromosome migration appears to be the most probable. It is suggested that an impeded division of the centromeres of the longest chromosomes gives the best explanation of the peculiar mitotic figures.

These results help to explain why benzoquinone and naphthoquinone have been considered as mitotic poisons of the colchicine type by several authors[3], while hydroquinone and other diphenols appeared to have in mice a typical radiomimetic effect[1]: the early modifications of mitosis described above have some resemblance to the colchicine effect (accumulation of metaphases), whereas later, when no more cells enter division, pycnosis and cellular disintegra[illegible]on sets in, as after irradiation. It is of interest to [illegible]te that mitotic abnormalities similar to those [illegible]strated above have been described as one of the [illegible]nary or 'physiological' effects of irradiation[6]. [illegible]search now in progress may eventually help to

Antagonism Between Molybdenum and Certain Heavy Metals in Plant Nutrition

It has been recognized in the literature that an excess of either manganese, zinc, copper, cobalt or nickel will induce iron-deficiency chlorosis in plants. Other toxic effects such as stunting and lower leaf necrosis may also occur. These effects have been confirmed in water-culture experiments with flax, conducted at the Plant Research Laboratory, Department of Agriculture, Burnley, Victoria.

In these experiments, it has been further shown that it is possible to reduce the severity of iron-deficiency symptoms, caused by an excess of any one of the above elements, by increasing the supply of molybdenum to the solution. Various concentrations of added molybdenum up to 20 parts per million have been used.

In the case of excess manganese (5–100 p.p.m.), which has been the heavy metal treatment most intensively studied, the added molybdenum reduced the severity of lower leaf necrosis, which is a characteristic manganese-toxicity symptom. A preliminary paper on this subject will be published in a forthcoming issue of the *Journal of the Australian Institute of Agricultural Science*. This describes experiments with flax. Manganese/molybdenum antagonism has since been demonstrated in water-culture experiments with peas, cabbages and tomatoes.

In Victoria, on highly acid soils, a previously undescribed disease of flax occurs which has been called 'lower leaf scorch'. Previous to the water-culture work outlined above, it was found that lower leaf scorch could be prevented by liming, and aggravated by sulphur, steam sterilization, or manganese sulphate. Affected plants were found to contain a higher manganese concentration than normal. In the past two seasons the disease has been prevented, in both pot and field experiments, by applying small amounts of ammonium molybdate (1–2 lb. per acre). In further pot experiments with highly acid soils (*p*H 4·8), heavy dressings of manganese sulphate (up to 10 cwt. per acre) caused severe lower leaf scorch. However, where ammonium molybdate (2 lb. per acre) was added with the heavy dressings of manganese sulphate, the severity [illegible] manganese-induced lower leaf scorch was mu[illegible] reduced. Applications of some samples of sup[illegible] phosphate have been effective in preventing lower-[illegible] scorch of flax. Such samples have been found [illegible]

but with a normal supply of manganese and iron, has shown a slight general chlorosis, and a necrosis of the lower leaves commencing at the edges. These symptoms appeared to be similar, if not identical, with those of lower leaf scorch or manganese toxicity.

Synonymy of the Nudibranch Genera *Pellibranchus* and *Okadaia*

Since the publication of a paper[1] describing *Pellibranchus cinnabareus* as a new genus and species of non-pelagic nudibranch mollusc, Dr. Nils H. J. Odhner, of the Riksmuseet, Stockholm, has pointed out to me that *Pellibranchus* is a synonym of *Okadaia* Baba[2]. *Okadaia* contains small nudibranchs less than 5 mm. in length, limaciform, head and foot not carinate; rhinophores simple, contractile, without sheaths; mouth slit-like; gills absent; anus and nephroproct opening slightly to the right of the mid-dorsal line, about a third of the way back from the head; genital orifices obliquely in front of the anus on the right side of the body; jaw plates absent; radula formula, 3, 0, 3; liver divided into three or four lobes; true heart not enclosed in a pericardium; gonads consisting of two or three testes and five or six ovaries; development is direct. These are the characters of the nudibranch described in my paper, and *Pellibranchus* is clearly a synonym of *Okadaia* which now contains *Okadaia elegans* Baba, 1930, the type from Japan, and *Okadaia* (= *Pellibranchus*) *cinnabareus* (Ralph, 1944) from New Zealand.

Both *O. elegans* and *O. cinnabareus* frequent the intertidal zone. Towards the beginning of October, *O. elegans* begins to lay eggs underneath stones. Adult animals and eggs of *O. cinnabareus* can be found under the surface of stones at all seasons of the year. *O. elegans* is most abundant from January to April. Specimens of *O. elegans* are known to occur along the Pacific Ocean side of Japan from Tomoika (Amakusa) to as far north as Akkeshi (Hokkaidô). At present *O. cinnabareus* is known only from tidal runnels along the shore at Island Bay, Wellington.

O. cinnabareus is distinguished from *O. elegans* principally on the structure of the teeth comprising the radula. The first lateral of *O. elegans* has one denticle outside the cusp and two inside, whereas in *O. cinnabareus* the first lateral has only one denticle, which is situated inside the cusp. The third lateral of *O. elegans* takes the form of a squarish plate; but in *O. cinnabareus* it is more conical. Baba[3] gives the colour of *O. elegans* as light orange-yellow. *O. cinnabareus* is bright red. Baba counted 27–54 heart-beats per minute through the transparent integument of *O. elegans*. It is not possible to count the heart-beats in *O. cinnabareus* as the integument is heavily pigmented and non-transparent. Full accounts of the two species have appeared in the *Japanese Journal of Zoology*[2] and the *Transactions of the Royal Society* [illegible] *Zealand*[1].

MASS-DEFECTS OF THE HEAVY ISOTOPES

By A. H. WAPSTRA
Instituut voor Theoretische Natuurkunde,
Rijks-Universiteit te Utrecht

IN preparing the tables for Prof. L. Rosenfeld's book[1] I noticed that an error was made in the mass-defects of the heavy isotopes as given in the "Isotopenbericht 1942" of Flügge and Mattauch[2]. The difference of the mass-defects $\Delta\varepsilon$ in every β-decay was taken equal to the maximum energies of the β-particles, eventually increased by the γ-energies. No correction was made for the fact that a neutron changes into a lighter proton, so that the mass-defect difference is

$$\Delta\varepsilon = 0{\cdot}754 \text{ MeV.} - E_{\beta}.$$

Because this error accumulates in each successive β-decay, the error in the mass-defects difference between the extreme members of each radioactive family is about 4 MeV.

In the accompanying table we give more correct data for the differences in mass-defects relative to Pb^{206}. For the α- and β-energies used, see refs. 3 and 4. The mass-defects of the thorium family are adjusted to those of the uranium family on the assumption that the mass-defects of the lead, polonium and thorium isotopes, all of which belong to the even-even type, should each lie on a parabola. This adjustment can be made with a mean error of 0·5 MeV.

The position of the isotopes of the actinium and neptunium families was more difficult to determine. We used for this purpose a special diagram[5]. In this diagram the difference of the mass-defects from a well-chosen linear function of the mass-number A is written instead of the isotopes in an A—n diagram (n = neutron-excess). This diagram permits the study of the energy surfaces in greater detail than has hitherto been possible. With its aid we discovered that to a close approximation the three energy surfaces (of the even-even, odd-odd and even-odd nuclei) are parallel even in detail: it was possible to bring the diagrams of the three kinds of isotopes on to one drawing by only varying the constant in the linear functions. This has been done[1] for the lighter elements (A less than 65) using the linear functions

$$\begin{aligned}&(\text{even-even})\ 9{\cdot}175\,A - 25{\cdot}0 \text{ MeV.}\\ &(\text{odd-odd})\ \ 9{\cdot}175\,A - 28{\cdot}5 \text{ MeV.}\\ &(\text{even-odd})\ 9{\cdot}175\,A - 27{\cdot}0 \text{ MeV.}\end{aligned}$$

The difference between the (ee)- and (oo)-surface is thus 3·5 MeV., and the (eo)-surface is almost midway between them. Now, from the results for the uranium family it is possible to deduce the difference between the (ee)- and (oo)-surface in the region of the heavy isotopes by assuming that the two (ee)- and the two (oo)-isotopes in it with mass-number 210 should be situated on two parallel parabolas. The difference is 2·03 MeV. If we may suppose that the (eo)-surface is situated halfway between the (ee)- and the (oo)-surfaces, we can give also the mass-defects of the (eo)-isotopes, that is to say, the actinium and neptunium families. It is thus necessary to see if the (eo)-surface is parallel to the other energy surfaces in this case also.

Po^{210}	RaF	22·79								
Pb^{206}	RaG	0								
Tl^{206}		−0·95								

For this purpose we have again used a similar diagram. The figures on this diagram of both new families were easy to find by assuming that the lead, polonium and thorium isotopes should be situated on the same parabolas we have already used for the uranium and thorium families. This adjustment was made with a mean error of 0·7 MeV. for the actinium family and 0·5 MeV. for the new neptunium family. This last result is interesting as showing that the experimental values given for the decay energies of these new isotopes are rather accurate. The reliability of the mass-defects we have found from them is still more strikingly confirmed by the fact that the resulting diagram exhibits a much better consistency than was expected. The linear functions used were :

$$\text{(ee) } 5{\cdot}5(A-206) + \varepsilon(\text{Pb}^{206})$$
$$\text{(oo) } 5{\cdot}5(A-206) + \varepsilon(\text{Pb}^{206}) - 2{\cdot}03$$
$$\text{(eo) } 5{\cdot}5(A-206) + \varepsilon(\text{Pb}^{206}) - 1{\cdot}0.$$

We feel justified, therefore, in placing the (oe)-isotopes midway between the (ee)- and (oo)-surfaces. By this means we have made the accompanying table of the differences of the mass-defects of the heavy isotopes from that of Pb^{206}. They are believed to have an error of about 0·8 MeV. Differences for members of the same family are much more accurate, except in the actinium family, where the decay energy of uranium Y (Th^{231}) is unknown. We have taken for its mass-defect that situated on the thorium parabola used above.

Notes added in proof. (*a*) The value for U^{236} in the diagram should be 16 instead of 6 ; (*b*) with the decay scheme of N. Feather (*Nature*, **160**, 749 ; 1947) the mass-defect of U^{239} in the table becomes 182·15 and its value in the diagram 17.

CONSTITUTION OF CERTAIN BINUCLEAR METALLIC CARBONYLS AND NITROSYLS

By Dr. R. V. G. EWENS

Guy's Hospital Medical School, London

JENSEN AND ASMUSSEN[1] have recently made some interesting suggestions concerning the nature of the bridge links in polynuclear complex inorganic compounds, and one of the examples they discuss is iron enneacarbonyl, $\text{Fe}_2(\text{CO})_9$. Now the X-ray evidence[2] shows that the structure is essentially that shown in Fig. 1,

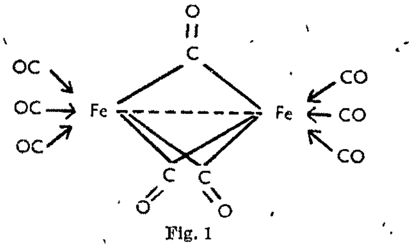

Fig. 1

in which a direct Fe–Fe link accounts for the observe interatomic distance and for the diamagnetism of th molecule. Without such a bond, each iron would b trivalent, with an effective atomic number of 35, a in the paramagnetic $\text{K}_3[\text{Fe(CN)}_6]$ and in the binuclea 1 : 10-phenanthroline iron (III) complex (Fig. 2)

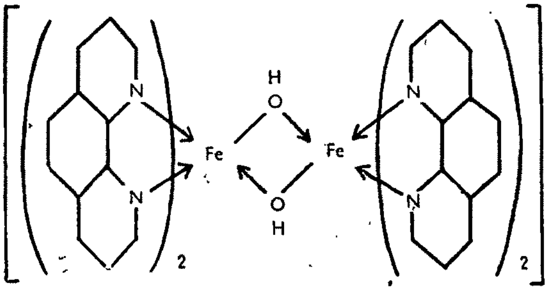

Fig. 2

where an unpaired electron spin is associated wit each iron (III) atom[3] : but with the metal–meta bond the effective atomic number becomes 36 as i the diamagnetic compounds $\text{K}_4[\text{Fe(CN)}_6]$ and Fe(CO)

Jensen and Asmussen make the alternative sugges tion that the diamagnetism of the enneacarbony could be accounted for by resonance between bridg structures which may readily be simplified (Figs. and 4) *without* the assumption of a metal–metal bond

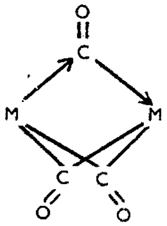

Fig. 3

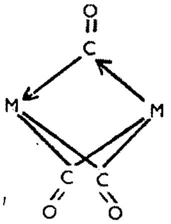

Fig. 4

While such a formulation gives even effective atomi numbers to both iron atoms, 34 to the 'donor' and 3 to the 'acceptor' (numbers which are not affected by the resonance $\text{O} \overset{\rightarrow}{\equiv} \text{C} \rightarrow M \sim \text{O} = \text{C} = M$ in th terminal carbonyl groups), and might thus explai the observed diamagnetism, it does not, in fact dispense with an Fe–Fe bond. For if these structure are written in the alternative way with $\overset{+}{B} - \overset{-}{A}$ instead of $B \rightarrow A$, they become Figs. 5 and 6. I

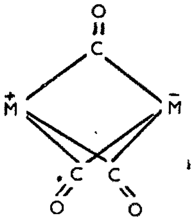

Fig. 5

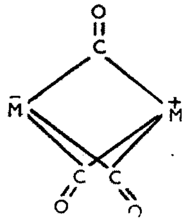

Fig. 6

is thus clear that Jensen's scheme simply replace the symmetrical covalent M—M link by a resonance hybrid $\overset{+}{M} : \overset{-}{M} \sim \overset{-}{M} : \overset{+}{M}$ derived from the extrem ionic forms. Such a mesomeric state is tantamount to a link with sufficient covalent character to justify the use of the single symbol Fe–Fe, any contribution from such ionic states being implied in the customary manner.

Moreover, Jensen and Asmussen's supposition demands a resonance between two valency states (formally II and IV). Now numerous complexes of this type are known and, as these authors point out elsewhere in the same paper, the resonance is associated with intense colour. But the colour of iron enneacarbonyl is only orange-yellow, and the cobalt carbonyl $Co_2(CO)_8$, the formulation of which entails the same difficulty, is but a pale yellow, so that this evidence certainly offers no support for Jensen and Asmussen's view.

It would, however, be very curious if this rare type of metal–metal linkage were confined to iron enneacarbonyl; but it appears certain that other examples exist. Thus the dimeric and diamagnetic cobalt tetracarbonyl $Co_2(CO)_8$ can be formulated as in Fig. 7,

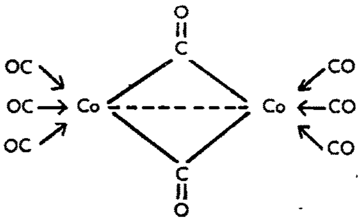

Fig. 7

in which the cobalt, initially with one electron more than iron, requires one carbonyl bridge less to become isoelectronic (effective atomic number 36) with the metal atom in the diamagnetic $K_3[Co(CN)_6]$ and the diamagnetic iron compounds above.

'Roussin's red salt' and its analogues form an even more interesting group of compounds, the structures of which may be explained in a similar manner. These compounds are all of the type $Fe(NO)_2X$, where X may be $—S^-K^+$ (the original red salt), —Cl[4], —I[5], $—S.C_2H_5$, $—S.C_6H_5$, or $—S.SO_3^-K^+$ (the thiosulphate). Of these the chloride and the ethyl and phenyl esters have been shown to be dimeric, while Roussin's red salt itself[6] and the thiosulphate[7] have been shown to be diamagnetic, so that we may fairly assume the degree of polymerization and the magnetic behaviour to be the same for all these substances. They may then be assigned the general structure shown in Fig. 8, in which each nitrosyl

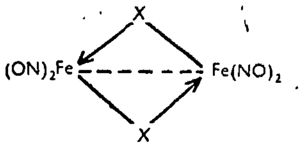

Fig. 8

group contributes three electrons to the metal atom (as in $\overset{=}{M} - \overset{+}{N} \equiv \overset{+}{\mathrm{O}} \sim \overset{+}{M} = \overset{-}{N} = \mathrm{O}$[9]). In addition, each iron atom acquires three electrons from the bridging groups and one from the Fe–Fe link, giving 26 + 2 × 3 + 3 + 1 = 36 as the effective atomic number.

An earlier view, that these compounds are really hyponitrites, has been criticized by Manchot[9], and is rendered the more unlikely by the observations that iron dinitrosyl dicarbonyl $Fe(NO)_2(CO)_2$, in which the NO groups are distinct[8], reacts smoothly with iodine[6] and with benzenethiol[10] to give the corresponding Roussin-type compounds. This being so, the above bridged structure is the only plausible alternative, and the Fe–Fe link is then necessary to explain the diamagnetism.

Even the more complicated Roussin's black salt $K[Fe_4(NO)_7S_3]$ can be explained on similar lines. A fuller account of this and other matters related to the above discussion will be published elsewhere in due course.

CHROMOSOMAL EVOLUTION IN THE EUROPEAN MOLE-CRICKET

By TUVIAH KUSHNIR

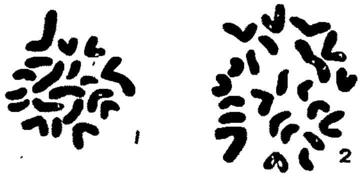
Department of Zoology, Hebrew University, Jerusalem

IT is well known that species belonging to the same genus frequently differ in their chromosomal numbers. Special interest is attached to this diversity, since it may furnish a clue to the mode of evolution of the species. Although reduction in number of chromosomes appears to occur fairly frequently, practically nothing is known about their increase in numbers except by polyploidy, which occurs very rarely in animals. The European mole-cricket (*Gryllotalpa gryllotalpa* L.) is a most interesting example of a progressive increase in chromosome number within the limits of the same species. It would appear that speciation based on diversification of chromosome numbers is here at work.

The species *G. gryllotalpa* may be divided into four geographical races which differ in their chromosomal numbers. The northern race found in Belgium, Germany, France and northern Italy has 12 chromosomes (10 autosomes and XY)[1,2]. In Roumania there is a second race with 14 chromosomes (12 autosomes and XY)[3]. A third race in central Italy is characterized by 15 chromosomes in the male (14 autosomes and X)[4], while a type with 17 chromosomes was observed in southern Italy[5]; the same type has recently been found by Barigozzi[6].

Barigozzi[7] and de Winiwarter[2] suggested that fragmentation of two pairs of anisobrachial metacentric chromosomes of the northern race may have given rise to the two additional small pairs characteristic of the central Italian type. This hypothesis is certainly much too simple, as it is well known that acentric fragments are non-viable. White[8], on the other hand, postulated that evolution occurred by reduction of the number of chromosomes, since two species of *Gryllotalpa*, namely, *G. borealis* and *G. africana* and a related genus *Scapteriscus*, have 23 chromosomes (22 autosomes and X).

In a cytological study of the Palestinian mole-cricket, which belongs to *G. gryllotalpa*, we observed two new races, one with 19 chromosomes (18 autosomes and X, Fig. 1), and the second with 23 (22 autosomes and X, Fig. 2). The first (19 chromosomes) is common throughout Palestine (Judean Hills, the coastal plain, Valley of Esdraelon, Beisan



Figs. 1 and 2. SPERMATOGONIAL METAPHASE OF MOLE-CRICKET: (1) PALESTINIAN RACE, 19 CHROMOSOMES; (2) DEAD SEA RACE, 23 CHROMOSOMES; FROM PREPARATIONS FIXED IN 15 PARTS PICRIC ACID, 5 PARTS FORMALIN, 1 PART 45 PER CENT ACETIC ACID

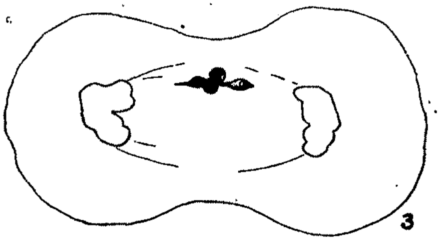


Fig. 3. TELOPHASE OF MEIOTIC DIVISION, AN OCTAD LAGGING IN EQUATORIAL PLANE, PREPARATION FIXED IN BOUIN'S SOLUTION. ALL SECTIONS 10 μ THICK, STAINED IN HEIDENHAIN'S HÆMATOXYLIN. × 2100

Valley and Galilee), while the second (23 chromosomes) is restricted to a single locality very close to the Dead Sea.

All the elements of the Palestinian race seem to be homologous with those of the central Italian race, except that six small chromosomes occur instead of only two of the same size which are found in the Italian type. In the Dead Sea race there are ten such small chromosomes. In the light of these facts, it was difficult to assume that the direction of evolution was towards reduction, as all the remaining elements appear identical in the three races, a fact which argues against the possibility of translocation. On the other hand, it is also difficult to assume that eight elements would disappear from the chromosome pattern, leading from the Dead Sea type to that of central Italy.

The behaviour of these chromosomes at meiosis was found to be peculiar. In approximately 13 per cent of the observed cases, certain chromosomes lag in the anaphase and telophase. These chromosomes, which can be identified as the small ones, remain as tetrads in the equatorial plane during the anaphase movement of the other dyads. Sometimes plates with octads are seen, linked by means of chiasmata (Fig. 3), a fact which clearly demonstrates the common origin of these small chromosomes. In most of these cases the normal separation of the dyads finally occurs, the dyads joining the nuclei almost at the termination of telophase. But in a considerable percentage of cases a whole tetrad passes to one daughter nucleus, and sometimes even an octad passes to one pole. As a result of this non-disjunction, among second spermatocytes there are cells containing eleven dyads as well as others containing only seven. Since spermatids with varying numbers of chromosomes are formed, one might expect to find mole-crickets with varying numbers of chromosomes, 17, 18, and 21. Examination of 140 mole-crickets from six localities in Palestine has shown that 19 is the only chromosomal number found. Hence it may be concluded that the exceptional gametes or the new types emerging from them are non-viable at some stage in development.

The six small chromosomes show no heteropycnosis at the meiotic prophase, whereas the two small chromosomes in the Italian race exhibit a typical heteropycnosis during meiosis, and become precociously condensed at prophase together with the X-element. In the light of this evidence, it is difficult not to conclude that we are dealing with the establishment of permanent from supernumerary chromosomes, in other words, a transition from hetero- to euchromatin. While the transformation of euchromatin to heterochromatin by mutation of active genes to inert ones is more frequently postulated by geneticists, the reversion of this process appears equally plausible.

It may be significant that heterochromatic chromosomes are still present in the Roumanian race and that they behave as typical supernumeraries, that is, their number in the population fluctuates. Thus mole-crickets with 15 or 16 chromosomes are found in addition to the common type with 14 elements[3]. In size and form the additional chromosomes correspond to those described in the Palestinian material. Supernumerary chromosomes of a similar type were also found in *G. africana*[4].

Due to their inertness, supernumerary chromosomes may increase in number in some individuals without causing conspicuous damage. On the other hand, Darlington claimed that in some cases (*Zea Mays*, *Cimex*, etc.) they possess adaptive advantages[9,10]. It may be that a further step involving a certain number of new viable mutations establishes them in certain types.

In this connexion it is interesting to note that the highest chromosome number among the Palestinian mole-crickets (23) is found in the Dead Sea locality, where temperature fluctuation and salinity of soil are extreme. It is an almost inevitable conclusion that the two additional pairs of small chromosomes contain a set of polygenes which enable this race to survive under extreme conditions.

The chromosomes of *G. africana* (23) from the southern Dead Sea fully conform to the description of previous authors[4]. They differ fundamentally from the 23 chromosomes of the Dead Sea race of *G. gryllotalpa*. The 23 chromosomes of *G. africana* can be arranged in a series of fours, which makes it probable that the species is a tetraploid.

Thus the number 24 (in the female) was reached twice by independent methods in the mole-crickets. Whereas in *G. africana* (and probably *G. borealis* and *Scapteriscus*) 24 were obtained by doubling of the original set of 12, in *G. gryllotalpa* a progressive accumulation of small (heterochromatic) chromosomes led to the establishment of a whole series of geographical races and found its climax in the Dead Sea race with the same number, 24. A fuller discussion of this problem and of the origin and behaviour of the small chromosomes will be published elsewhere.

I would like to express my appreciation to Dr. E. Goldschmidt for her aid and encouragement during the progress of this work.

WRITTEN EXPRESSION IN SCIENCE

A CONFERENCE at the City Boys' School, Leicester, convened and presided over by the headmaster, Mr. R. W. Crammer, was held on March 12 to discuss the problem of the difficulty experienced by science graduates in writing reports and the ways in which the grammar schools could help in overcoming it. Dr. U. R. Evans, reader in the science of metallic corrosion in the University of Cambridge, who had raised the matter in the University Senate House, addressed the conference in a private capacity. There were seventy people present, including the heads of grammar schools in the City and County of Leicester, their English and science masters and mistresses and representatives from Leicester University College, the Domestic Science College and the Women's Training College. The conference was welcomed not only because of the importance of its subject but also because it brought together representatives of the grammar schools and of institutions of higher education for the discussion of a common concern.

In his address, Dr. Evans said that one of the few serious complaints raised to-day against the young scientific graduate refers to his alleged inability to express findings in a written report. Since a report still represents the best means available for a scientific worker to share his knowledge with others, the complaint is a serious one, and suggests that the writing of English does not receive sufficient attention at schools and universities. The dreary character of many papers printed to-day in scientific journals provides further evidence. Complaints are heard of the excessive length of papers submitted for publication, and it is often felt that the mode of presentation is such that a paper fails to hold the attention of those whom it ought to interest; a common fault is the omission to make clear the reasons for selecting the subject of investigation, and to emphasize the significance of the results for those working on other subjects.

The main trouble seems to arise from the fact that often the young scientific worker has no love for writing. Whatever disciplinarians may say, it is doubtful whether anyone makes a real success of a ask which gives him no sort of satisfaction. Enhusiastic and hard-working experimenters show an obvious reluctance to produce reports by the appointed day, and require a surprising length of time o produce a very simple memorandum. Even if the results, when ultimately completed, were perfect, the bvious disinclination to use the pen in the communication of ideas reveals an unsatisfactory state of affairs. This aversion to writing is often shown by men who are extremely successful in explaining their ideas by word of mouth.

It is significant that the difficulties affect many who have attained conspicuous success in the examination hall; there they may have been helped, in manner of which they were scarcely aware, by the fact that they were writing down facts or arguments previously read in a book or heard at a lecture. When suddenly confronted with the task of discovering for themselves a sequence of words to express something hitherto unreduced to verbal form, they experience the same difficulty as is met with y someone who, at the age of twenty, starts to express himself in French or German. In both cases the difficulty would probably be lessened if the first attempts were made at an earlier age.

There are certain grammatical problems met with in reports which, unless solved, can endanger correct understanding. A report usually refers to work accomplished within some definite period, and starts with a statement of the position at the outset, largely based on the work of the previous period; here the correct employment of pluperfects and perfects often presents difficulty. Next will come the programme for the new period, and now the periphrastic constructions needed to express plans made in the relatively distant past for work in the immediate past sometimes involve perplexity—especially since subjunctives and conditionals must often be introduced (for example, where there has been doubt as to how the plans would work out). In the experimental section the problems of expression are mainly technical, but the author's interpretation of his results, involving comparisons with the views of others, may necessitate passage between *oratio recta* and *oratio obliqua*, which some writers find far from easy.

The understanding of a report can be greatly helped by consistent use of the different classes of headings available for division into sections and subsections; conversely, if headings are used indiscriminately, understanding is hindered. Again, punctuation used on any consistent plan will assist comprehension; stops thrown in at random are worse than useless.

It would seem that definite instruction, which need not occupy many hours of school time, is needed in certain subjects—such as punctuation and systematic division into sections and subsections; but that most of the troubles would pass away if the boys received plenty of practice under conditions favourable to the cultivation of a taste for writing. Essay-writing seems to be accepted as the standard method of gaining experience in the arrangement of words, but only a certain type of essay will aid report-writing—namely, that dealing with some subject which the writer has never before seen or heard described in words. A commentary upon a stage-play or film may be a better choice than a discussion of matters described in printed books. The reading of books by great authors is advocated by many. Clearly such reading is worth while for its own sake, but it is doubtful how far literary masterpieces can help the writing of scientific reports; it is scarcely a compliment to their authors to suggest that a style skilfully developed for one purpose should be adopted for another. Nevertheless, the reading of certain authors may serve to enlarge the reader's vocabulary and may show him how the skilful selection of words can introduce delicate shades of meaning into the picture presented. Perhaps others may be found to provide examples of terseness—a matter of practical importance in days when the supply of paper is short and the patience of readers not inexhaustible.

Mr. Crammer, in opening the discussion, pointed out the psychological and sociological difficulties encountered by the grammar schools in the teaching of written expression in English. The grammar schools have in recent years admitted more and more pupils coming from homes in which there is little or no culture or encouragement in the reading of good books or conversation, let alone in writing. The social atmosphere generally has tended to counteract the training in writing given in the schools, a point which was taken up and emphasized by subsequent speakers, who laid stress on the decline in reading due to the cinema and the radio, as well as on the absence of æsthetic and literary standards in the home.

Others blamed the too early and the excessive specialization in the schools, a fault which the latter referred back to the universities and the increasingly high standard of attainment required by them for the award of scholarships. The 'objective' tests, consisting of one-word answers often used in the examinations for entrance to the grammar schools, were also criticized as not encouraging the teaching and practice of continuous written English in primary schools.

The vital importance of frequent practice in writing was admitted, but the burden of marking it imposed upon the teachers of English would be intolerably heavy if more practice was to be given without an increase in free periods for marking. The position would be better if all teachers, and not only those directly responsible for the teaching of English, regarded themselves as teachers of English as well as of their special subjects, and took the trouble to correct faulty English in all written work. One speaker rightly objected to the division of English into 'Science' English and 'Literary' English; the science graduate's difficulty in written expression is part of the general problem of the teaching of English to all pupils, irrespective of the forms of their later specializations.

After Dr. Evans had replied to the various points raised, Mr. Crammer summed up the discussion. It was clear, he said, (1) that there was general agreement about the necessity of all teachers, and not only the teachers of English, making the writing of English their concern, and (2) that continuous practice in writing is essential and must go on into and throughout the university course as well as throughout school life. It was worth considering whether in science scholarship examinations an essay and a general paper should be made compulsory and should be given considerable weight in deciding the awards. A committee representative of both schools and colleges was formed to investigate the problem further with a view to the formulation of constructive suggestions.

PHYSIOLOGY AND BIOCHEMISTRY OF FATS AND LIPOIDS

A PHYSIOLOGICAL symposium on fats, arranged by Le Centre National de la Recherche Scientifique and supported by the Rockefeller Foundation, was held in Paris during January 5–12. The meetings took place in the Department of General Physiology (Prof. G. Schaeffer) at the Sorbonne. Prof. E. F. Terroine presided.

The conference was opened with a paper by Prof. A. C. Frazer (Great Britain), who described new methods for the study of fat absorption problems, and presented the results of his investigations on the nature of the intestinal emulsifying system and hydrolysis of triglyceride. Prof. P. Desnuelles (France) reported experiments which have confirmed and extended Prof. Frazer's work on the formation of di- and mono-glycerides as end-products of pancreatic lipolysis. Miss E. Le Breton (France) spoke of her demonstration of A- and B-lecithinases and cholesterol esterase in the pancreatic juice. Its possible importance in the fat absorption mechanism was discussed. Prof. F. Verzar (Switzerland) reviewed his work on fat absorption, dealing particularly with his experiments relating the adrenal cortex to fat absorption. Prof. A. C. Frazer followed with a detailed account of the experimental work of his school on the intracellular and distributive phases of fat absorption. Prof. P. E. Verkade (Holland) gave a short paper which illustrated the inadequacy of the alleged solvent action of bile salt solutions for fatty acids. In the subsequent discussion, agreement was reached on the questions of intraluminar emulsification, the probable importance of hydrolysis, phosphorylation and the adrenal cortex in the fat absorption mechanism, and the possible occurrence of particulate absorption of fat. The extent of hydrolysis, amount of material absorbed in particulate form, the function of phosphorylation, and the nature of the influence of the adrenal gland on the fat absorption mechanism, were fully discussed.

Prof. T. Cahn (France) described investigations in dogs designed to determine the effect of muscular exercise, fasting, hyperthermia and pancreatectomy on fat mobilization; and Dr. G. Clément (France) discussed the effects of unilateral denervation on fat mobilization in rats. The relationship between B-lecithinase and cholesterol esterase in the blood, and its influence in the formation of cholesterol esters, was raised by Miss E. Le Breton. Prof. M. Machebœuf (France) described his work on lipoprotein complexes in blood and gave an account of his extensive investigations into the lipoid content of fractionated plasma proteins, and interesting observations on the replacement of lipoids in lipoprotein by substances of similar molecular structure. Prof. E. Chargaff (United States) gave a survey of the association between lipoids and proteins in biological systems, discussing the possible nature of the forces concerned in the construction of these complexes, with numerou illustrations from his own experiments.

Prof. A. C. Frazer presented an account of som new methods which had been developed for the study of particulate fat in a protein environment. H described his experiments on blood fat and artificia particulate systems. He also reported X-ray dif fraction studies on nerve lipoprotein which demon strated the importance of water in lipoprotei structure, and other useful data. A lengthy discussio on all aspects of blood fat and the methods of stud of lipoprotein complexes ensued. Later, Prof. E Chargaff spoke of his work on blood coagulation with particular reference to the part played b lipoproteins in these reactions.

Prof. K. Bernhard (Switzerland) described th biological degradation of fatty acids. With extensiv references to his own work in this field, he discusse β-, ω- and multiple-oxidation. He suggested tha β-oxidation is most likely to occur under natura conditions and that ketones are mainly formed b condensation of the 2-carbon fragments split off b β-oxidation. Prof. P. Verkade discussed the relatior ship between the ingestion of carbohydrate an triundecylin and the excretion of undecanedioic aci in the urine in healthy human subjects. Administra tion of carbohydrate causes an increase of dioi aciduria. The possible significance of liver glycoge in these experiments was discussed. Prof. R. I Barnes (United States) gave a detailed account recent work on ketogenesis. He described the variou steps in the elucidation of this problem by the u of isotope-labelled materials, and put forward a ne hypothesis to explain the anti-ketogenic action of carbohydrates. A session was also devoted to the consideration of lecithin degradation. Dr. M. Kahane (France) described his investigations into the presence of water-soluble choline esters in the blood and tissues, and Prof. J. Roche (France) gave an account of enzymological studies on the hydrolysis of phosphoryl choline and phosphoryl colamine by phosphatases. The structure and hydrolysis of egg lecithin were discussed by Prof. P. Fleury (France).

The nutritional importance of essential unsaturated fatty acids was discussed after a survey of work in this field had been given by Prof. K. Bernhard and Prof. R. H. Barnes. Miss E. Le Breton described experiments on fatty acid dehydrogenases. She described the relationship of certain vitamins and phosphorylation to the activity of these desaturases. Their possible significance in the problem of essential fatty acids was discussed.

In the concluding session, Dr. C. Paquot (France) described his work on the autoxidation of fats, and presented theoretical considerations, both on this question and on the subject of anti-oxidants. Prof. A. Chevallier (France) described apparent relationships between the oxidation and ultra-violet absorption of glycerides, and Prof. P. Dubouloz (France) spoke of his researches on anti-oxidants in relation to vitamin A. He discussed the mechanism of anti-oxidant action and described preliminary experiments on the physiological properties of peroxidized lipids. Prof. R. H. Barnes gave a survey of recent work carried out in the United States on anti-oxidants, and the development of oxidative rancidity in fats. He emphasized the possible importance of rancidity in biological processes.

The official business of the symposium was completed in eight days and was carried through in a most cordial atmosphere. The full proceedings, including summaries of the various discussions, will be published in due course in the *Archives des Sciences Physiologiques*.

METABOLIC ASPECTS OF CONVALESCENCE

THE *Transactions* of two conferences on "Metabolic Aspects of Convalescence" referred to below* make very stimulating reading. Although they are often so specialized that possibly only those who have themselves worked in the particular fields will fully appreciate the significance of some of the questions and answers, yet the general impression left after reading them is that one has made the 'Grand Tour' and become personally acquainted with very interesting people and ideas.

With the exception of the symposium on bone metabolism (*Trans. Fourteenth Meeting*), the reports are more in the nature of short progress notes rather than balanced statements of experiment and interpretation. As one contributor remarks, "The data presented are of a preliminary nature and are offered in the hope that they may stimulate discussion".

Convalescence is concerned with the repair of injured tissues and the restoration of normal functioning so that, in effect, the study of its metabolic aspects is very similar to the general study of growth and development. The vast mass of interrelated factors—which scientific workers are only at the beginning of unravelling—is well illustrated by the wide range of subjects covered at these conferences. The reader finds himself switched from "A Comparison of the Effect of Testosterone Propionate on the Enzyme Content of the Kidney and Liver of Castrated and Normal Rats" to "Metabolic Studies before and after Operation of Chronically Ill Patients fed entirely by Vein", or from "Partition Chromatography on Paper" to "Peritoneal Lavage in Uremia". There were sixty-five reports at the thirteenth meeting and thirty-five at the fourteenth. Between them they seem to cover the ground remarkably thoroughly, and anyone whose work is concerned with any aspect of growth or development is likely to find some point of interest which may well give a new turn to his line of thought. The symposium on bone metabolism (a subject to which a large part of earlier meetings in the series has been devoted) forms a contrast to the rest of the papers. The reports presented are longer and more detailed; there is a clear exposition of contrasting hypotheses and a series of very clear photographs.

These reports pose questions rather than provide answers, but they give the impression of being full of helpful clues and well worth studying.

M. W. GRANT

---

* Conference on Metabolic Aspects of Convalescence. *Trans.* Thirteenth Meeting, Nawshon Island, Woods Hole, Mass., June 11, 1946. Pp. ii+232. 2 dollars. *Trans.* Fourteenth Meeting, New York, Nov. 2–13, 1946. Pp. ii+190. 2.25 dollars. (Josiah Macy, Jr., Foundation, 65 Park Avenue, New York, 1947.)

FORTHCOMING EVENTS

(*Meeting marked with an asterisk * is open to the public*)

Monday, April 5

FARMERS' CLUB (at the Royal Empire Society, Craven Street, Strand, London, W.C.2), at 2.30 p.m.—Dr. T. Dalling and Dr. A. W. Stableforth: "Bovine Mastitis".

PHYSICAL SOCIETY, LOW-TEMPERATURE GROUP (joint meeting with the INSTITUTE OF REFRIGERATION, at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Prof. G. Eichelberg: "Heat-Pump Problems and Industrial Realizations".

SOCIETY OF ENGINEERS (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. C. G. Vokes: "Filtration".

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 8.15 p.m.—Mr. John Lawrence: "The Russian Land and History".

Monday, April 5—Tuesday, April 6

SOCIETY OF CHEMICAL INDUSTRY (in the Mathematics Lecture Theatre, Royal College of Science, Huxley Building, Exhibition Road, London, S.W.7).—Symposium on "Detergents, Wetting and Emulsifying Agents".

Monday, April 5

At 2.15 p.m.—"Synthetic Detergents".

Tuesday, April 6

At 2.15 p.m.—"Wetting Agents and Auxiliary Products".

Tuesday, April 6

ROYAL STATISTICAL SOCIETY, RESEARCH SECTION (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5.15 p.m.—Mr. C. R. Rao: "The Utilization of Multiple Measurements in Problems of Biological Classification".

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP (joint meeting with the GLASGOW SECTION and the GLASGOW AND DISTRICT SECTION of the ROYAL INSTITUTE OF CHEMISTRY, in the Gas Showrooms, Sauchiehall Street, Glasgow), at 2.30 p.m.—Dr. E. C. Bate-Smith: "Refrigeration in Germany"; Mr. H. J. Bunker: "War-time Production of Food Yeast in Germany"; at 7 p.m.—Mr. J. F. Hearne: "German Albumen Substitutes"; Mr. C. B. Brown: "German Synthetic Detergents".

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 5 p.m.—Mr. Leon Underwood: "African Art and its Place in Art Tradition".
